**Abstract.** Forecasts of Pacific jet variability are used to predict stratosphere-to-troposphere transport (STT) and tropical-to-extratropical moisture exports (TME) during boreal spring over the Pacific-North American region. A retrospective analysis  
10 first documents the regionality of STT and TME for different Pacific jet patterns. Using these results as a guide, Pacific jet hindcasts, based on zonal-wind forecasts from the European Centre for Medium-Range Weather Forecasting Integrated Forecasting System, are utilized to test whether STT and TME over specific geographic regions may be predictable for subseasonal forecast leads (3-6 weeks ahead of time). Large anomalies in STT to the mid-troposphere over the North Pacific, TME to the west coast of the United States, and TME over Japan are found to have the best potential for subseasonal  
15 predictability using upper-level wind forecasts. STT to the planetary boundary layer over the intermountain west of the United States is also potentially predictable for subseasonal leads, but likely only in the context of shifts in the probability of extreme events. While STT and TME forecasts match verifications quite well in terms of spatial structure and anomaly sign, the number of anomalous transport days is underestimated compared to observations. The underestimation of the number of anomalous transport days exhibits a strong seasonal cycle, which becomes steadily worse as spring progresses into summer.

## 20 1 Introduction

Mass transport is important to many aspects of Pacific-North American climate, including: stratosphere-to-troposphere transport (STT) of ozone to the planetary boundary layer, which has negative impacts on human health (Fiore et al. 2003; EPA US 2006; Langford et al. 2009; Lefohn et al. 2011); STT to the free troposphere, which is needed to estimate the North American background distribution of ozone (Fiore et al. 2014, Cooper et al. 2015, Young et al. 2018); and water vapor  
25 transport, which contributes to precipitation variability (Ralph and Dettinger 2011; Mahoney et al. 2016; Guan et al. 2015; Gershunov et al. 2017). Because of these impacts, identifying time periods when transport forecasts might be skillful on subseasonal timescales (forecasts 3-6 weeks into the future) is recognized as having high societal value (e.g., Lin et al. 2015; Baggett et al. 2017 and references therein).

30 Skillful subseasonal transport forecasts hinge, in large part, on the skillful prediction of atmospheric teleconnections (Baggett  
et al. 2017; DeFlorio et al. 2019). Initial studies of subseasonal teleconnection variability suggested that enhanced predictability  
might occur during spring when strong El Niño-Southern Oscillation (ENSO) conditions are present (Barnston 1994;  
Branković et al. 1994; Branković and Palmer 1997). However, more recent studies suggest that, overall, teleconnections (Wang  
and Robertson 2019) and transport (DeFlorio et al. 2019) on subseasonal timescales tend to be most predictable during winter.  
35 Indeed, one reason to expect predictability to be lower in spring is that Pacific teleconnection patterns become increasingly  
sensitive to the location and scale of tropical forcing as the Pacific jet undergoes its seasonal transition (Newman and  
Sardeshmukh 1998; Barsugli and Sardeshmukh 2002; discussed in more detail below).

Still, even if teleconnections and transport are more predictable during winter on average, skillfully predicting the atmospheric  
40 circulation during spring is important in the context of both STT and water vapor transport. For example, STT of ozone that  
affects surface air quality occurs primarily during spring (e.g., Lefohn et al. 2001; Langford et al. 2009; Lefohn et al. 2011;  
Langford et al. 2012; Olsen et al. 2013; Škerlak et al. 2014; Lin et al. 2015). Likewise water vapor transport during spring is  
also important for many regions of the Pacific basin and North America (e.g., Cayan and Roads 1984, Lee et al. 2014, Swain  
et al. 2016, Mundhenk et al. 2016). Thus, here we seek to explore the circumstances whereby skillful transport predictions  
45 might be possible during the important, yet potentially less predictable spring season.

Stratosphere-to-troposphere transport and water vapor transport occur via distinct physical pathways. In midlatitudes, STT  
occurs mainly via two mechanisms: stratospheric potential vorticity (PV) intrusions, which include tropopause folds, PV  
streamers, and PV cutoffs (Reed and Danielson 1958; Hoerling et al. 1993; Langford and Reid 1998; Shapiro 1980; Sprenger  
50 et al. 2007; Škerlak et al. 2015); and transverse circulations in jet exit regions (Langford et al. 1998; Langford 1999). Intense  
water vapor transport events also arise via several distinct, though interrelated, physical processes, including so-called  
'atmospheric rivers', warm-conveyor belts, and tropical moisture exports (Zhu and Newell 1998; Stohl and James 2005;  
Knippertz and Martin 2007; Knippertz and Wernli 2010; Newman et al. 2012; Madonna et al. 2014; Pfahl et al. 2014; Knippertz  
et al. 2013; Ralph et al. 2018; Sodemann et al. 2020). In this study, we focus on spring season STT that extends downwards to  
55 the mid-troposphere and planetary boundary layer (PBL), and long-range tropical-to-extratropical water vapor transports,  
hereafter referred to as tropical moisture exports (TME; see Knippertz et al. 2013 for a detailed discussion of TME).

STT and TME have very different seasonal cycles in terms of timing and geography, which is readily observed in monthly  
mean climatologies (Fig. 1; see Section 2 for a detailed description of STT and TME, which are both taken from the database  
60 of Sprenger et al. 2017). Over western North America, STT of mass (and ozone) that reaches the PBL peaks in spring (Fig. 1,  
left column; see also, Škerlak et al. 2014; Albers et al. 2018 and references therein). Despite the strong storm track located  
over the North Pacific, deep STT into the PBL is limited over the ocean due to a shallow marine boundary layer. In contrast,  
STT of mass extending downwards into the middle troposphere (500 hPa), peaks during January and February and then slowly

decreases thereafter (Fig. 1, middle column). TME also undergoes a seemingly smooth transition during winter and spring, with an initial peak extending from Hawaii to the western US during February, followed by a slow recession of transport westward, whereby a secondary peak occurs near Japan during May (Fig. 1, third column; see also Knippertz and Wernli 2010; Mundhenk et al. 2016; Gershunov et al. 2017). The different regional and temporal characteristics of the STT and TME seasonal cycles shown in Fig. 1 are in part a reflection of the different physical processes that govern them, as outlined above. However, at least a portion of STT and TME seasonality and variability are linked by one important commonality: they are both directly modulated by large-scale Rossby waves (e.g., Ryoo et al. 2013; Albers et al. 2018), which themselves owe their propagation and breaking patterns to the strength and location of the subtropical and polar front jets (Hoskins and Ambrizzi 1993; Scott and Cammas 2002; Abatzoglou and Magnusdottir 2006; Hitchman and Huesmann 2007; Mundhenk et al. 2016; Olsen et al. 2019). For example, high TME is often observed on the western edge of blocking anticyclones in the North Pacific, where air is rising (Mundhenk et al. 2016), while STT occurs east of the block, where sinking air and PV intrusions frequently develop (Sprenger et al. 2007). This means that the variability, and as we will show, the predictability, of both types of transport are dependent on the seasonal cycle of the Pacific jet.

Sometime between early March and late April, the Pacific jet undergoes a transition – which typically occurs very abruptly – from being strong and largely zonally contiguous between Asia and North America to being weak, with a discontinuity in the jet that spans most of the Pacific basin (Nakamura 1992; Newman and Sardeshmukh 1998; Hoskins and Hodges 2019; Breeden et al. 2020). The characteristics of this transition, and its relationship to forms of low-frequency variability that might be predictable on subseasonal timescales (e.g., ENSO) have been explored in the context of STT of mass and ozone. For example, Breeden et al. 2020 demonstrated that early season jet transitions (mid-to-late March), which are more common during La Niña conditions, are characterized by enhanced mass transport to the PBL (see also, Lin et al. 2015 and references therein). Conversely, late transitions (mid-to-late April) have weaker transport to the PBL although the association to El Niño is somewhat weaker. However, these analyses are retrospective, and it remains unclear whether forcings such as ENSO – and the resulting teleconnections – are actually forecast well enough to be useful when making subseasonal transport predictions.

While the predictability of mass transport on daily timescales is typically limited to less than two weeks (Lavers et al. 2016; DeFlorio et al. 2018), weekly averages of dynamical variables can occasionally have skill out to 3-6 weeks (e.g., Wang and Robertson 2019; Buizza and Leutbecher 2015; Albers and Newman 2019). This evokes the possibility that forecasts of atmospheric transport, which may be harder for models to explicitly predict on subseasonal timescales, might be successfully inferred from forecasts of more predictable or better constrained dynamical variables. Indeed, similar ideas have been successfully applied to assess the predictability of atmospheric blocking on seasonal timescales (Pavan et al. 2000) and precipitation on daily timescales (Lavers et al. 2014; Lavers et al. 2016). Here we assess the potential predictability of transport during spring based on the predictability of zonal wind variance associated with the Pacific jet. We do so by considering a very simple conditional probability: if 200 hPa zonal winds have a high (positive or negative) loading on a particular 200 hPa

Pacific basin zonal wind pattern, then what will the corresponding shift in the probability of STT or TME be during those time periods? We first answer this question in the context of a retrospective analysis (1979-2016), which allows us to understand the regionality of STT and TME for different jet patterns. Then, using the retrospective results as a guide, we utilize Subseasonal-to-Seasonal Prediction Project database (Vitart et al. 2017) zonal wind hindcasts (1997-2016) from the European Centre for Medium-Range Weather Forecasts to test whether STT and TME over specific geographic regions may be predictable for subseasonal forecast leads (weeks 3-6). For both the retrospective and hindcast analyses, STT and TME are taken from the ETH-Zürich Feature-based climatology database (available for years 1979-2016; Sprenger et al. 2017), which allows us to apply a single, self-consistent measure of transport for both the retrospective (1979-2016) and hindcast (1997-2016) analysis periods.

## 2 Pacific jet and transport data

### 2.1 Jet variability

Jet variability over the Pacific-North American region is represented via empirical-orthogonal functions (EOFs), which are based on ERA-Interim (Dee et al. 2011) monthly mean (March-May, MAM) anomalies of 200 hPa zonal wind (cosine latitude weighted  $10^{\circ}$ - $70^{\circ}$  N and  $125^{\circ}$ - $270^{\circ}$  E) for the 1979-2016 period. Anomalies were created by removing the first four annual harmonics of the 1979-2016 daily climatology. Using monthly averages instead of daily or weekly values is motivated in part by the suggestion of Newman et al. (2012) that a large fraction of ocean-to-continent transport arises from low-frequency variability rather than individual synoptic events. Using monthly values also significantly boosts the variance explained by the leading three EOFs to nearly 60% versus <20% for daily values (e.g., Feldstein 2000). We use a bootstrap method to test for EOF degeneracy (North et al. 1982) and find that the first three EOFs (Fig. A1), which represent 25%, 21%, and 11% of the total MAM monthly mean wind variance, are reasonably well-separated and have robust spatial patterns (see Appendix for details). Hereafter we refer to the first three EOFs (and their corresponding PC time series) as EOF1 (PC1), EOF2 (PC2), and EOF3 (PC3).

While EOFs 1-3 are significantly correlated with several commonly used climate indices (Table 1), we make no inference that the EOF patterns represent dynamical or physical “modes” of the climate system (Monahan et al. 2009). Indeed, the significant correlations between each of our PC time series and multiple teleconnection indices indicates that the variance of our EOFs almost certainly results from a convolution of external forcing and internal variability across multiple timescales (e.g., Straus and Shukla 2002). Evidence for this assertion can be found by noting that while EOF1 is essentially uncorrelated with the NOAA Oceanic Niño Index (ONI) (correlation of 0.16 and not significant), EOF1 is one-month lag correlated with EOF2 (correlation 0.66, significance level >95%), which is itself highly correlated with the ONI index (correlation 0.78, significance level >95%). Thus, with one exception (considered in the Discussion) we simply use the EOFs as a data compression tool that helps to isolate the largest scale flow patterns that we anticipate will have the best chance for prediction.

130 To evaluate the potential predictability of Pacific jet variability, we use hindcasts (1997-2016) of 200 hPa zonal wind from the European Centre for Medium-Range Weather Forecasting Integrated Forecasting System (ECMWF IFS CY43R1/R3, model operational in 2017), which were obtained from the Subseasonal-to-Seasonal Prediction Project database (Vitart et al. 2017). Hindcasts are ‘coarse-grained’ in time via a 7-day running-mean and in space via regridding to a fixed 2.5-degree longitude/latitude grid. Anomalies are computed by removing the lead dependent climatology, which also serves as a mean  
135 bias correction (e.g., Buizza and Leutbecher 2015; Monhart et al. 2017). Hindcasts are computed as three-week averages for weeks 3-5 (i.e., days 15-35). The 3-week averages are then projected onto the EOF patterns described above. We also computed results for other averaging periods including weeks 3-4 and 3-6, as well as individual week 3, 4, and 5 forecasts, but settled on weeks 3-5, because we found that this window provided the most skillful transport forecasts. Specifically, averaging several weeks together increased skill (i.e., an extension of the ‘forecast skill horizon’, see for example, Younas and Tang 2013; Buizza  
140 and Leutbecher 2015), while extending the forecast window out all the way to week 6 degraded forecast skill because the forecast zonal wind anomaly amplitudes become very small compared to the verification anomaly amplitudes. The IFS hindcast PC time series are verified against ERA-Interim-based PC time series prepared in an identical manner.

To help verify that the zonal wind EOF patterns are highlighting Pacific jet variability (in Sect. 3.1), we compare the EOFs to a upper tropospheric jet stream climatology (Koch et al. 2006; Sprenger et al. 2017), which is itself based on ERA-Interim.  
145 The jet climatology (1979-2014) is based upon vertical averaging of zonal and meridional winds between 100-500 hPa at every horizontal grid point, where a ‘jet event’ at each grid point is detected when the vertically averaged wind exceeds  $30 \text{ ms}^{-1}$ . This procedure yields a frequency of upper tropospheric jet events at each grid point.

## 2.2 Transport composites

To examine stratosphere-to-troposphere mass transport and tropical-to-extratropical water vapor transport, we use six ETH-  
150 Zürich Feature-based ERA-Interim Climatologies (Sprenger et al. 2017): stratosphere-to-troposphere mass transport to 500 hPa ( $\text{STT}_{500}$ ), which provides an estimation of transport into the free troposphere, and stratosphere-to-troposphere transport to the planetary boundary layer ( $\text{STT}_{\text{PBL}}$ ) (Sprenger et al. 2003, Škerlak et al. 2014); and a climatology of tropical-to-extratropical moisture/water vapor transport (TME), (Knippertz and Wernli 2010). The STT climatologies (1979-2016) are based on Lagrangian parcel trajectories calculated using the LAGRANTO Lagrangian transport model (Wernli and Davies 1997;  
155 Sprenger and Wernli 2015), where stratosphere-to-troposphere mass trajectories are considered as exchange ‘events’ if they have 48-hour stratospheric, followed by 48-hour tropospheric, residence times. We use both monthly mean and daily mean climatologies of  $\text{STT}_{500}$  and  $\text{STT}_{\text{PBL}}$ , all of which have units of number of mass exchange events per 6-hourly time step. TME climatologies (1979-2016) are calculated via LAGRANTO water mass trajectories that originate in the tropics and reach at least  $35^\circ \text{ N}$  with a water mass flux greater than  $100 \text{ g kg}^{-1} \text{ m s}^{-1}$ ; we use monthly mean and daily mean TME climatologies  
160 where units are given as the number of TME events per 6-hourly time step.

For our retrospective transport analysis, we composite STT and TME for months when the zonal-wind PC time series were larger than 1 STD. For the hindcasts, we use a slightly weaker 0.8 STD threshold in order to boost the number of samples given the relatively short length of the subseasonal-to-seasonal hindcast database (1997-2016). We chose to keep the STD threshold as high as possible though, because higher amplitude anomalies likely correspond to periods of higher forecast skill (Compo and Sardeshmukh 2004; Van den Dool and Toth 1991; Johansson 2007). Importantly, the choice of threshold does not qualitatively change our results. Hindcast transport composites are based on time periods when weekly average *forecasts* of zonal-wind PC time series were predicted to exceed 0.8 STD. For hindcast verification composites, the composites are based on periods when the *verification* weekly average zonal-winds PC time series exceeded 0.8 STD. This procedure typically means that the verification composites include more samples because, as we will show, the weeks 3-5 IFS forecasts systematically underestimate the amplitude of the zonal wind PC time series and thus do not exceed the STD threshold as often as is observed.

We also briefly discuss the connection between STT and climatologies of tropopause folds (Sprenger et al. 2003; Škerlak et al. 2014), PV streamers (Wernli and Sprenger 2007), and PV cutoffs (Wernli and Sprenger 2007). Tropopause folds are defined as regions where a vertical profile contains three crossings of the dynamical tropopause, with additional criteria applied to ensure that the folded airmass is ‘stratospheric’ (e.g., enclosed airmass must have  $PV > 2$  PV units and cannot be of diabatic origin). Shallow, medium, and deep tropopause folds were considered, but only shallow and medium depth folds were found to be relevant. PV streamers (thin filaments of stratospheric air) are identified using a geometric contour searching algorithm, while PV cutoffs are identified as stratospheric airmasses ( $PV > 2$  PV units) that are isolated and fully-embedded within the troposphere. PV streamers and cutoffs were considered on isentropic surfaces between 305-340 K, but only the most relevant surfaces are shown. Units for folds, streamers, and cutoffs are events per 6-hourly time step.

### 2.3 Units and significance testing

While the original units of all of the ETH-Zürich climatologies are frequencies (jet frequency, STT, tropopause folds, PV streamers, PV cutoffs, and TME), all of our figures, except for the climatologies (Fig. 1), are presented in units of standard deviations. That is, for every variable, we calculate anomalies from climatology and then divide by the anomaly standard deviation (z-scoring). Thus, a unit of ‘1 STD’ equates to a one standard deviation anomaly, where the standard deviation is calculated individually for each specific time period considered (e.g., the STD normalization for a March monthly mean is different from the STD normalization used for a three-week forecast period in March).

When comparing forecast and verification transport probability density functions (PDFs), we evaluate significance via a combination of bootstrap confidence intervals (10,000 ensembles with replacement) and two-sample Kolmogorov-Smirnov distribution tests (KS-test; Marsaglia et al. 2003; Hollander et al. 2013), where the later tests whether the shape and location of two empirical distributions are significantly different. The PDFs themselves are created by taking box-area means of STT

or TME for a specified geographic region at every forecast time step and using each as a ‘sample’. The PDFs are then calculated via kernel density estimation based on the collection of all samples for either the forecasts or verifications.

### 3 Results

#### 195 3.1 Retrospective analysis

The first three EOF patterns of the 200 hPa zonal wind all exhibit anomalies that correspond to some amount of extension/retraction and/or latitudinal shifting of the Pacific jet compared to climatology (Fig. 2). This interpretation is confirmed by compositing ETH feature-based jet frequencies for time periods with high EOF loading (PC amplitude  $>1$  STD), which yields jet frequency distributions that correspond extremely well with each of the first three EOF wind patterns  
200 (Supplementary Fig. S1). This suggests that the amount of wind variance explained by each of the individual EOFs is sufficiently large that when the PC magnitude is high there are notable corresponding shifts in the location of the Pacific jet stream. While the EOF patterns likely combine jet variability due to both the subtropical and polar front jets (Koch et al. 2006), a strong jet stream of either type will act as a waveguide for Rossby waves (e.g., Schwierz et al. 2004; Rivière 2010 and references therein) with an increased frequency of STT (e.g., Shapiro and Keyser 1990) and TME (e.g., Higgins et al. 2000;  
205 Sprenger et al. 2017).

To evaluate the jet-transport connection, we consider STT and TME for time periods with high zonal wind EOF loading (absolute value of PCs  $>1$  STD). Because the patterns of the STT and TME anomaly composites are so similar for both EOF phases, we show only the negative EOF pattern; see Supplement Figs. S2-S4 for the positive phase. STT<sub>500</sub> maxima match the  
210 EOF wind patterns quite well (Fig. 3, top row), with positive (negative) STT<sub>500</sub> anomalies tending to occur along the northern flanks of the regions of stronger (weaker) winds (Koch et al. 2006), and hence increased (decreased) jet frequency. The correspondence of higher STT<sub>500</sub> with higher windspeeds, suggests that transverse circulations around the jet play a key role in transport, and confirms that the EOF-based STT<sub>500</sub> anomalies are related to variations in the North Pacific storm track (Škerlak et al. 2014). The STT<sub>500</sub> anomalies are most closely associated with shallow to medium depth tropopause folds (Figs.  
215 S5 and S6) and PV cutoffs along the 310 K isentropic surface (Fig. S7).

STT<sub>PBL</sub> on the other hand (Fig. 3 middle row), have maxima slightly downstream of the 500 hPa maxima, which reflects the fact that deep STT tends to occur as maturing Rossby waves amplify and PV streamers become increasingly stretched and filamented along isentropic surfaces that slope equatorward and downwards towards the surface (see for example, discussion  
220 of Fig. 5 in Škerlak et al. 2014; see also Reed and Danielson 1958; Shapiro 1980; Shapiro and Keyser 1990; Wernli and Bourqui 2002; Sprenger et al. 2003, Appenzeller et al. 1996, Wernli and Sprenger 2007). In addition, as the PV streamers become more filamented, isolated regions of high PV stratospheric air often become fully detached as PV cutoffs. Indeed, MAM STT<sub>PBL</sub> appears to be closely associated with PV streamers and PV cutoffs along the 310 and 305 K isentropic surfaces

(Figs. S8 and S9, respectively). In contrast to  $STT_{500}$ ,  $STT_{PBL}$  does not appear to be strongly associated with tropopause folds (not shown; see also Supplemental Fig. S1(e) of Škerlak et al. 2015), though some caution should be exercised when interpreting the relative importance of tropopause folds, PV streamers, and PV cutoffs for deep STT as shown here, because previous authors, using alternative techniques, have found that tropopause folds play an important role in deep STT (e.g., Shapiro 1980; Langford et al. 2009; Breeden et al. 2020 and references therein). Anomalous TME also corresponds well with the EOF patterns (Fig. 3, bottom row), except that the anomalies are on the southern edge of the positive EOF wind patterns, which is due to the tendency for strong TME to occur along the warm sector of a breaking Rossby wave (Bao et al. 2006; Knippertz et al. 2013).

While all of the transport composites are physically consistent with the EOF patterns, and hence jet variability, the  $STT_{500}$  and TME composites have a much more robust signal compared  $STT_{PBL}$ . That the  $STT_{PBL}$  is weaker is not entirely surprising because while a high percentage of upper level breaking waves extend downwards to the mid- to upper troposphere, subsequently causing associated  $STT_{500}$  and TME, only a small subset of these waves will achieve the needed amplitude and depth to extend all the way to the PBL. Moreover, transport to the  $STT_{PBL}$  is also dependent on the depth of the PBL, which tends to be relatively shallow until late spring to early summer when convective heating begins to increase (Seidel et al. 2012; Škerlak et al. 2014; Breeden et al. 2020). Nevertheless, all of the composites provide a basis for the expectation that Pacific jet variability can be used as a predictor for transport over landmasses of interest, including the western United States, southern Alaska, and Japan.

### 3.2 Potential predictability of jet shifts and transport

While subseasonal forecasts of teleconnection indices are known to exhibit reasonable correlation-based skill (Wang and Robertson 2019), the amplitude of the anomalies is often quite weak compared to observations (Yamagami and Matsueda 2020). Thus, the relevant question here is, do forecast models predict jet variability well enough – in terms of both correlation and anomaly amplitude – to provide guidance for subseasonal transport forecasting?

For weekly forecasts, the correlation between the forecasted and verified zonal wind PCs is ‘skillful’ (correlations  $>0.5$ - $0.6$ , Hollingsworth et al. 1980; Arpe et al. 1985; Murphy and Epstein 1989) within the deterministic timeframe (weeks 1-2) for all three EOFs (Table 2). Beyond week 2, however, the PC1 and PC3 correlations drop off rapidly, with the skill of predicting PC3 almost completely limited to synoptic timescales. On the other hand, PC2 retains useful skill all the way out to forecast week 6, which may be due to its stronger relationship to ENSO (Table 1). These correlations suggest that only the first two PCs retain enough skill to be useful on subseasonal leads. The same result is true for the weeks 3-5 forecast window (Fig. 4), where forecast-verification correlations for both PC1 and PC2 are near or above 0.5, while PC3 exhibits very low correlation-based skill. In terms of the PC amplitudes of the weeks 3-5 forecasts, both PC1 and PC2 regularly exceed our 0.8 STD threshold, while the PC3 amplitude rarely exceeds it. Thus, while EOF3 is related to large transport anomalies over land regions

of interest (e.g.,  $STT_{PBL}$  and TME over North America), it is unfortunately not predictable on subseasonal timescales (similar results are also found for EOFs 4 and higher). We therefore focus on predicting transport via PC1 and PC2.

260 The number of observed instances (verifications) when the PC1 and PC2 amplitudes exceeds 0.8 STDs exhibits a seasonal cycle (Fig. 5), though the degree of overlap of the confidence intervals suggests that the seasonal cycle is more pronounced for EOF2 than for EOF1. The situation is a bit more complicated if the individual phases of each EOF are considered (see Supplement, Fig. S10), though the small sample sizes make conclusive inferences difficult. Nevertheless, the slow decay of observed PC1 and PC2 exceedances (i.e., large amplitude jet events) between March and May is qualitatively consistent with  
265 previous studies documenting the seasonality of jet activity and Pacific baroclinic wave amplitudes (Nakamura 1992; Koch et al. 2006). Unfortunately, the number of PC1 and PC2 exceedances predicted by the IFS at 3-5 week lead times has a much stronger seasonal cycle compared to observations, with early spring having many more exceedances than for late spring for both phases of PC1 and PC2 (Fig. 5 and Supplement S10). This implies that the transport anomalies outlined next are more predictable, and hence the composites more heavily weighted, for the periods before the jet undergoes its spring transition  
270 (Newman and Sardeshmukh 1998; Breeden et al. 2020).

Based on the regions with the largest transport anomalies (Fig. 3) for the more predictable PC1 and PC2 time series (Fig. 4), we chose four subregions within the full Pacific domain to examine the potential predictability of STT and TME: EOF1-based  $STT_{500}$  for the North Pacific, which includes southern Alaska and the Russian Far East; EOF2-based  $STT_{PBL}$  for the western  
275 to intermountain-western US; EOF1-based TME for the western US; and EOF2-based TME for the West Pacific (Japan and far eastern Asia). These subregions are highlighted by the boxes in Figs. 6a, 7a, 8a, and 9a, respectively. To provide context for the four subregion forecasts, we first show forecast and verification transport anomalies for the entire Pacific domain. For each of the four full domain figures (Figs. 6-9), the top two panels show verification transport composites, which are based on times when the *verification* zonal wind PC time series amplitude is greater than  $\pm 0.8$  STD (black lines in Fig. 4), while the  
280 bottom two panels show corresponding transport composites, except for time periods when the *forecasted* zonal wind PC time series amplitude is greater than  $\pm 0.8$  STD (orange lines in Fig. 4). For comparison, the months that are included in the retrospective composites (Fig. 3) are highlighted by the light red and blue shading in Fig. 4 (note that the time periods when the week 3-5 time series exceed the  $\pm 0.8$  STD threshold do not always match the red and blue shading regions, because the shaded regions highlight periods when the monthly mean time series exceeded the monthly 1 STD threshold). The pattern  
285 correlations between the forecast and verification transport composites for the full domains in Figs. 6-9 (not just for the boxed in areas) are included in the forecast titles for both EOF phases. Transport predictability for the four boxed subregions is subsequently evaluated via PDFs of transport for the forecasts and verifications (Fig. 10). Beyond the four region/transport-type combinations just mentioned,  $STT_{500}$  and TME were found to be potentially predictable for EOFs 1 and 2 over several additional subregions of the central Pacific basin, but because those results are similar to what we discuss below, they are not  
290 shown.

STT<sub>500</sub> based on the EOF1 forecast is qualitatively consistent with the verification-based composite for both positive and negative EOF phases (Fig. 6), though the STT<sub>500</sub> pattern is better reproduced for the negative phase (pattern correlation of 0.49 vs. 0.75 for the positive vs. negative phases, respectively). In addition, the verification composites show an asymmetry between opposite EOF1 phases in the amount of STT<sub>500</sub>, which is also accurately forecasted, with the negative EOF phase exhibiting peak values in the 0.75-1.25 STD range vs. 0.25-0.5 STDs for the positive EOF phase. This asymmetry is likewise reflected in the forecast and verification PDFs of STT<sub>500</sub> for the North Pacific subregion (Fig. 10a), where the median for the positive EOF1 phase is weakly negative, while the negative EOF1 phase has a greater than +0.5 STD median anomaly. The only noteworthy difference between the North Pacific forecast and verification PDFs is that the forecast-based PDF is shifted towards more positive values than the verification-based PDF. Regardless, the confidence intervals for the medians of the positive vs. negative phases of the forecast-based PDFs are very well-separated and the underlying distributions are different according to a KS-test, which suggests that the predicted shifts in transport are significant. We also evaluated forecasts of STT<sub>500</sub> for various subregions over populated land masses (e.g., the western US), but the resulting verification and forecast PDFs were not significantly different, which reflects the fact that STT<sub>500</sub> peaks over the North Pacific portion of the storm track (Fig. 3a).

For EOF2-based STT<sub>PBL</sub> over the western US, the verification composite is consistent with the retrospective composites (cf., Figs. 7a,b and Fig. 3e), however, the pattern is much weaker. Nevertheless, the forecast- and verification-based STT<sub>PBL</sub> composites (Fig. 7c,d) and PDFs for the western US subregion (Fig. 10b) do agree quite well. However, the STT<sub>PBL</sub> distribution is notably shifted away from zero only for the negative EOF phase and the confidence intervals for the medians overlap, which suggests that the STT<sub>PBL</sub> forecasts are probably borderline in their usefulness for most forecast periods. Still, the forecasted STT<sub>PBL</sub> do represent different distributions according to a KS-test, so the change in the shape of the tails of the distributions may be of some practical use for prediction of extreme STT<sub>PBL</sub> events.

There are several potential reasons why the STT<sub>500</sub> forecast and retrospective composite pattern amplitudes compare quite well (c.f. Fig. 3a and Fig. 6), while the STT<sub>PBL</sub> forecast and verification patterns are weaker than their retrospective counterparts (c.f. Fig. 3e and Fig. 7). First, STT<sub>PBL</sub> over the Pacific-North American region tends to be largest for two circumstances: regions with high orography and time periods when the PBL height is particularly high. These two circumstances coincide over the western to intermountain-western US (Škerlak et al. 2014; Breeden et al. 2020) during MAM, which coincides with the box area (Fig. 7a) used for our STT<sub>PBL</sub> PDF calculations (Fig. 10b). Unfortunately, PBL heights do not get particularly high until mid- to late spring (see Fig. 5c of Breeden et al. 2020), which is the time period when Pacific jet forecasts are the least skillful (Fig. 5b). A second potential issue is that only a small percentage of overall STT events are deep enough to reach the lowermost troposphere (e.g., Škerlak et al. 2014 find that 36% of SST events reach 500 hPa, while only 5% reach 800 hPa, see their Fig. 4), which may magnify sampling issues related to the much smaller hindcast period (1997-2016) compared

325 to the longer period (1979-2016) used for the retrospective analysis. We attempted to address the sampling issue by expanding the forecast averaging window from 3 weeks to 4 weeks, however, using an expanded 4 week averaging window yielded fewer well-forecasted periods, which also resulted in a weaker STT<sub>PBL</sub> pattern.

The TME forecasts match the verifications very well, for both EOFs, and for both phases of each EOF, with basin-wide pattern correlations ranging from 0.57 to 0.88 (Figs. 8-9). In addition, the magnitude of the anomaly values for both EOFs are notable, with both TME phases exhibiting anomalies in the 0.5-1.25 STD range over relatively large portions of the Pacific domain. Interestingly, positive TME centered over Alaska is predicted very well for the positive phase of EOF1 (Fig. 8a,c) and the negative phase of EOF2 (Figs. 9b,d), yet it is unclear if this pattern represents a reliably predictable form of TME because neither of the corresponding TME composites for the longer time record retrospective analysis show anomalies over Alaska (cf., Figs. 8 and 9 to Figs. 3g and 3h, respectively). In contrast, the forecasted patterns of TME between Japan and the west coast of the US (south of 55° N) are quite consistent with the jet (Figs. 1 and S1) and TME (Fig. 3, bottom row) patterns from the retrospective analysis, which suggests that TME over broad regions of the Pacific basin may be reasonably predictable during spring. Indeed, the western US and West Pacific subregion TME PDF shifts are robust and match the verification PDFs very well (Fig. 10c and d, respectively). This is particularly true for the West Pacific where the median shift in TME transport is nearly +/- 1 STD for each EOF phase, and the PDF forecast and verification PDFs are nearly identical.

## Discussion and conclusions

Many ‘modes’ of climate variability are known to be associated with anomalous atmospheric transport. For example, stratosphere-to-troposphere mass and ozone transport to the PBL over North America is known to be influenced by ENSO (Breedon et al. 2020; Lin et al. 2015 and references therein), while the frequency of atmospheric rivers is thought to be modulated by a variety of climate phenomena, including ENSO, the Madden-Julian oscillation, and the quasi-biennial oscillation (Guan et al. 2012; Lee et al. 2014; Kim and Alexander 2015; Guan et al. 2015; Mundhenk et al. 2016; Guirguis et al. 2019). However, retrospectively isolating such associations, which is equivalent to conducting a ‘perfect model’ forecast, does not assure that current operational forecast models can successfully predict those relationships, particularly on subseasonal timescales (e.g., Lavers et al. 2016; Baggett et al. 2017). Nevertheless, some teleconnection and transport patterns appear to be potentially predictable on subseasonal timescales (e.g., Mundhenk et al. 2018; Wang and Robertson 2019; Pan et al. 2019; DeFlorio et al. 2019; Yamagami and Matsueda 2020), though these forecasts are typically found to occur during boreal winter.

Our analyses have shown that stratosphere-to-troposphere transport (STT) to at least 500 hPa and long-range tropical-to-extratropical moisture exports (TME) over the Pacific-North American region can potentially be skillfully predicted on subseasonal timescales (3-5 weeks ahead of time) during boreal spring. The transport forecasts themselves were inferred from

ECWMF IFS-based forecasts of Pacific jet variability. IFS Pacific jet forecasts for four Pacific-North American subregions are associated with significant shifts in the probability of anomalous transport, including: STT into the free troposphere over the North Pacific (Fig. 10a); STT into the planetary boundary layer over the intermountain-western US (Fig. 10b); TME over the west coast of the US (Fig. 10c); and TME to Japan and far eastern Asia (Fig. 10d). While the forecasted shifts in transport probability match verifications quite well, one deficiency is apparent: the IFS is able to predict the sign of the zonal wind PC time series with reasonable success (Table 2 and Fig. 4), yet it consistently struggles to maintain enough zonal-wind PC amplitude relative to the substantial weather-related noise (compare amplitude of forecast and verification time series in Fig. 4). This results in an underestimation of the number of anomalous transport days compared to observations (Fig. 5), which degrades the estimation of the transport probabilities (Fig. 10).

The underestimation of the number of anomalous transport days exhibits a strong seasonal dependence, which becomes quite acute during April and May (Fig. 5). This implies that either overall teleconnection predictability decreases as spring proceeds, or alternatively, the IFS is simply unable to skillfully predict large amplitude jet anomalies with consistency beyond early-spring. While it is beyond the scope of the current study to explore which one of these possibilities is responsible for the lack of consistent late spring skill, this is clearly an important question, because the first possibility would be a fundamental feature of the climate system, while the latter would be a model-based constraint that might theoretically be improved. Of course, these two possibilities are not mutually exclusive, because the increasing sensitivity of Pacific-North American teleconnections to tropical forcing at smaller spatial scales during the spring jet transition (Newman and Sardeshmukh 1998) may be inherently less predictable, yet also more difficult to accurately model. That said, despite the IFS underestimation of the number of days with anomalously strong jet patterns (Fig. 5), the IFS is still able to identify roughly 15% (PC1) and 30% (PC2) of all spring days (March-May) that are anomalous, which suggests that using upper-level winds to forecast transport may currently be possible.

For the three types of transport that we have evaluated here, STT into the free troposphere and TME are the most robustly predicted, at least in terms of shifts of the average and extremes of their transport distributions (Fig. 10). STT to the PBL over the western US, on the other hand, mainly exhibits a change in the shape of the tails of the transport distributions, but a rather weak shift in the median (i.e., the shift of the medians of the two EOF2 phases have confidence intervals that are strongly overlapping, Fig. 10b). This has implications for the suggestion that ENSO may be used to predict air quality related to STT of ozone during spring (e.g., Lin et al. 2015 and Albers et al. 2018 and references therein). Similar to previous retrospective analyses (e.g., Lin et al. 2015; Breeden et al. 2020), we find that mass transport to the PBL is associated with ENSO (Fig. 11), where here, we have composited  $STT_{PBL}$  based on periods when the NOAA ONI is greater than 0.8 STDs from the historical mean, which yields an equivalent number of samples to our EOF2-based results. The ONI-based (retrospective) transport composites look very similar to our earlier EOF2-based retrospective results (cf., Figs. 11a and b to Figs. 3e and S3c, respectively. For proper comparison, note that PC2 and ONI are negatively correlated). Moreover, the transport PDFs for the

intermountain-western US subregion based on PC2 versus ONI, for both ENSO phases, are drawn from the same distributions according to a two-sample Kolmogorov-Smirnov test (Fig. 11c). This close correspondence is due to the high correlation between the ONI and PC2 time series (Fig. 11d). Yet, because we have found STT<sub>PBL</sub> predictions related to EOF2 to be significant only in terms of shifts in the tails of the distributions (cf. Fig. 10b and 11c), our results suggest that at best, ENSO may be harnessed to provide STT<sub>PBL</sub> forecast guidance on subseasonal timescales for extreme events only. Complicating matters further in the context of ozone transport to the PBL (as opposed to simply mass transport as investigated here), is that predictions based on ENSO will likely be even more difficult because STT of ozone is also modulated by the seasonal variability of the available reservoir of ozone in the extratropical lower stratosphere (Olsen et al. 2013; Neu et al. 2014; Albers et al. 2018). That said, because it is doubtful that Nino-3.4-based indices like ONI capture the full dynamical scope of ENSO variability (Penland and Matrosova 2006; Capotondi et al. 2015), the complete impact of ENSO on STT<sub>PBL</sub> predictability certainly deserves further study.

### **Data Availability**

The ERA-Interim reanalysis data used in this study is available through the National Center for Atmospheric Research Consortium for Atmospheric Research Data Archive: <https://rda.ucar.edu/>. The STT, TME, and jet ERA-Interim feature-based climatology data is available from <http://eraiclim.ethz.ch/>. ECMWF IFS hindcast data is available via the S2S Prediction Project (<http://s2sprediction.net/>).

### **Author Contributions**

John R. Albers wrote retrospective and hindcast analysis code, created the figures, and wrote the manuscript. Amy H. Butler, Melissa L. Breeden, Andrew O. Langford, and George N. Kiladis provided comments and edited the manuscript.

### **Competing Interests**

The authors declare that they have no conflict of interest.

### **Acknowledgements**

The authors would like to thank Michael Sprenger for graciously making the 6-hourly ETH Feature-based data available, which made this study possible. The authors also wish to thank two anonymous reviewers whose comments improved the science and clarity of the manuscript. JRA and AHB were funded in part by NSF grant #1756958. MLB was funded by NOAA Climate and Global Change Postdoctoral Fellowship Program, administered by UCAR's Cooperative Programs for the Advancement of Earth System Science (CPAESS) under award # NA18NWS4620043B. The authors would like to thank Yan Wang for preparing the IFS S2S data and Benjamin Moore, who helped furnish the 6-hourly TME data.

	WP	PNA	ONI
PC1	-0.66 (0.00)	0.44 (0.00)	0.16 (0.1)
PC2	-0.38 (0.00)	-0.09 (0.35)	-0.78 (0.00)
PC3	-0.31 (0.00)	-0.56 (0.00)	-0.05 (0.64)

**Table 1:** Correlations between MAM monthly average PC time series and various climate indices, with p-values in parentheses. The West Pacific pattern (WP) and Pacific-North American pattern (PNA) and NOAA Oceanic Niño Index (ONI) are taken from NOAA Center for Weather and Climate Prediction (NOAA CPC).

	<i>week 1</i>	<i>week 2</i>	<i>week 3</i>	<i>week 4</i>	<i>week 5</i>	<i>week 6</i>
<b>PC 1</b>	0.97 [0.96,0.97]	0.78 [0.75,0.83]	0.57 [0.51,0.63]	0.42 [0.35,0.49]	0.3 [0.22,0.38]	0.31 [0.23,0.39]
<b>PC 2</b>	0.97 [0.96,0.98]	0.86 [0.84,0.88]	0.74 [0.7,0.78]	0.71 [0.66,0.75]	0.68 [0.63,0.72]	0.66 [0.61,0.71]
<b>PC 3</b>	0.94 [0.93,0.95]	0.68 [0.63,0.72]	0.38 [0.3,0.45]	0.21 [0.13,0.3]	0.12 [0.03,0.2]	0.09 [0.0,0.18]

**Table 2:** Correlations between MAM weekly average PC time series of IFS hindcasts and ERA-Interim verifications. 95<sup>th</sup> percentile confidence intervals are shown in square brackets underneath each correlation coefficient. All p-values are less than 0.05 when all data is used in the forecast-verification correlation calculations; however, if the correlation calculations are repeated instead using every third forecast (to take into account autocorrelation in the forecast time series), then PC3 has large p-values (0.12 and 0.32) at weeks 5 and 6, respectively, while all other PC correlations at all forecast leads remain <0.05.

635

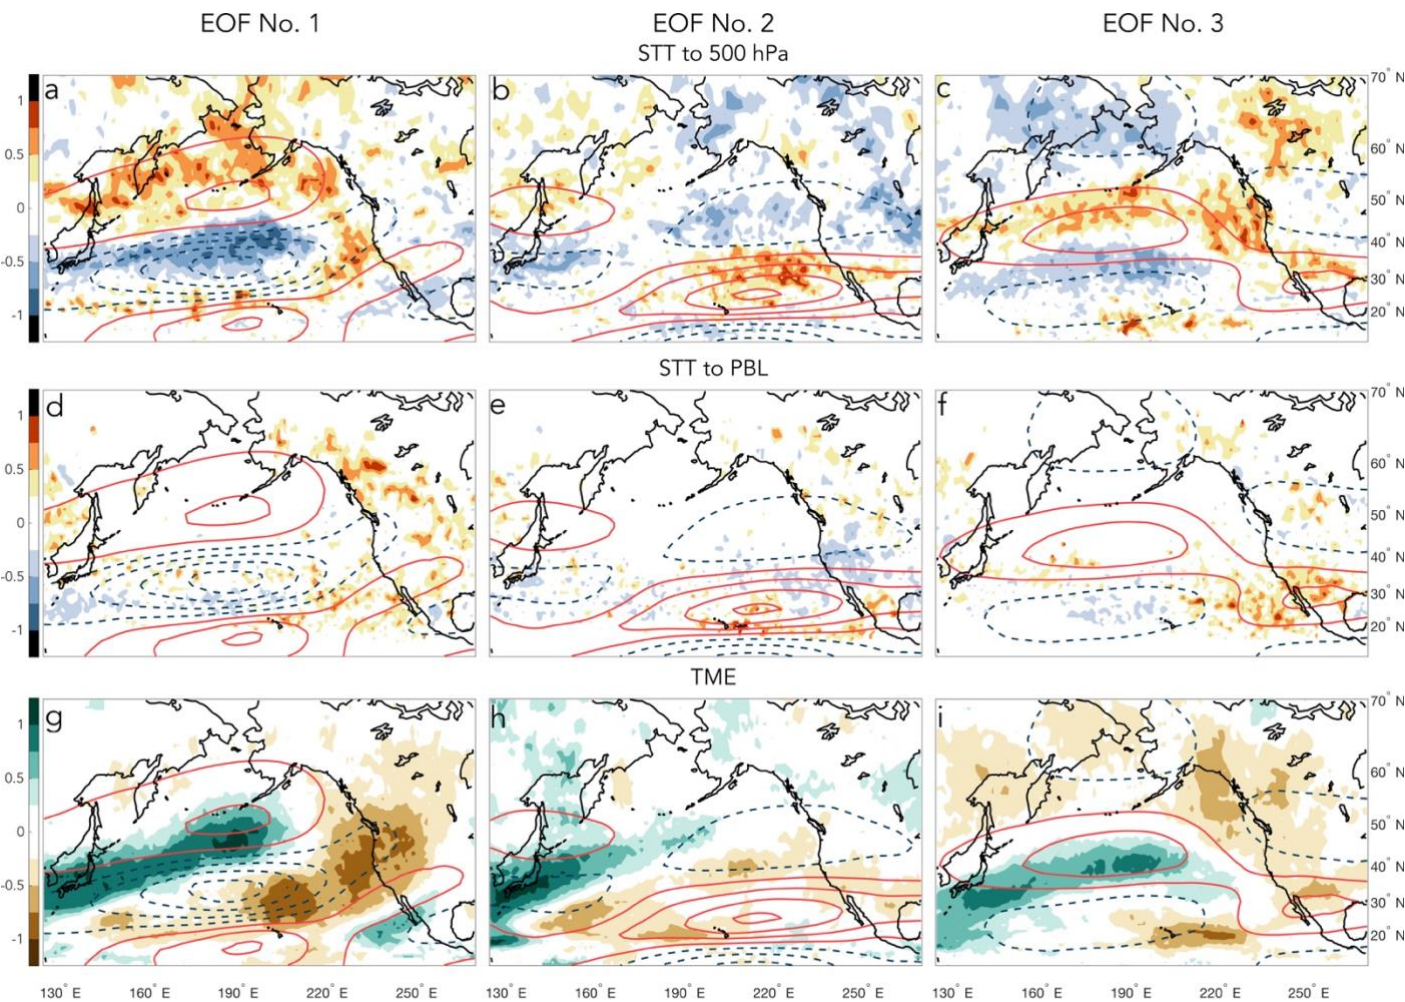

**Figure 1:** Monthly average climatologies (1979-2014) of STT to the PBL (left column), STT to 500 hPa (middle column), and TME (right column). Units for all panels are event frequencies (events/6-hourly time step), where each of the relevant events types are defined in Sect. 2.2.

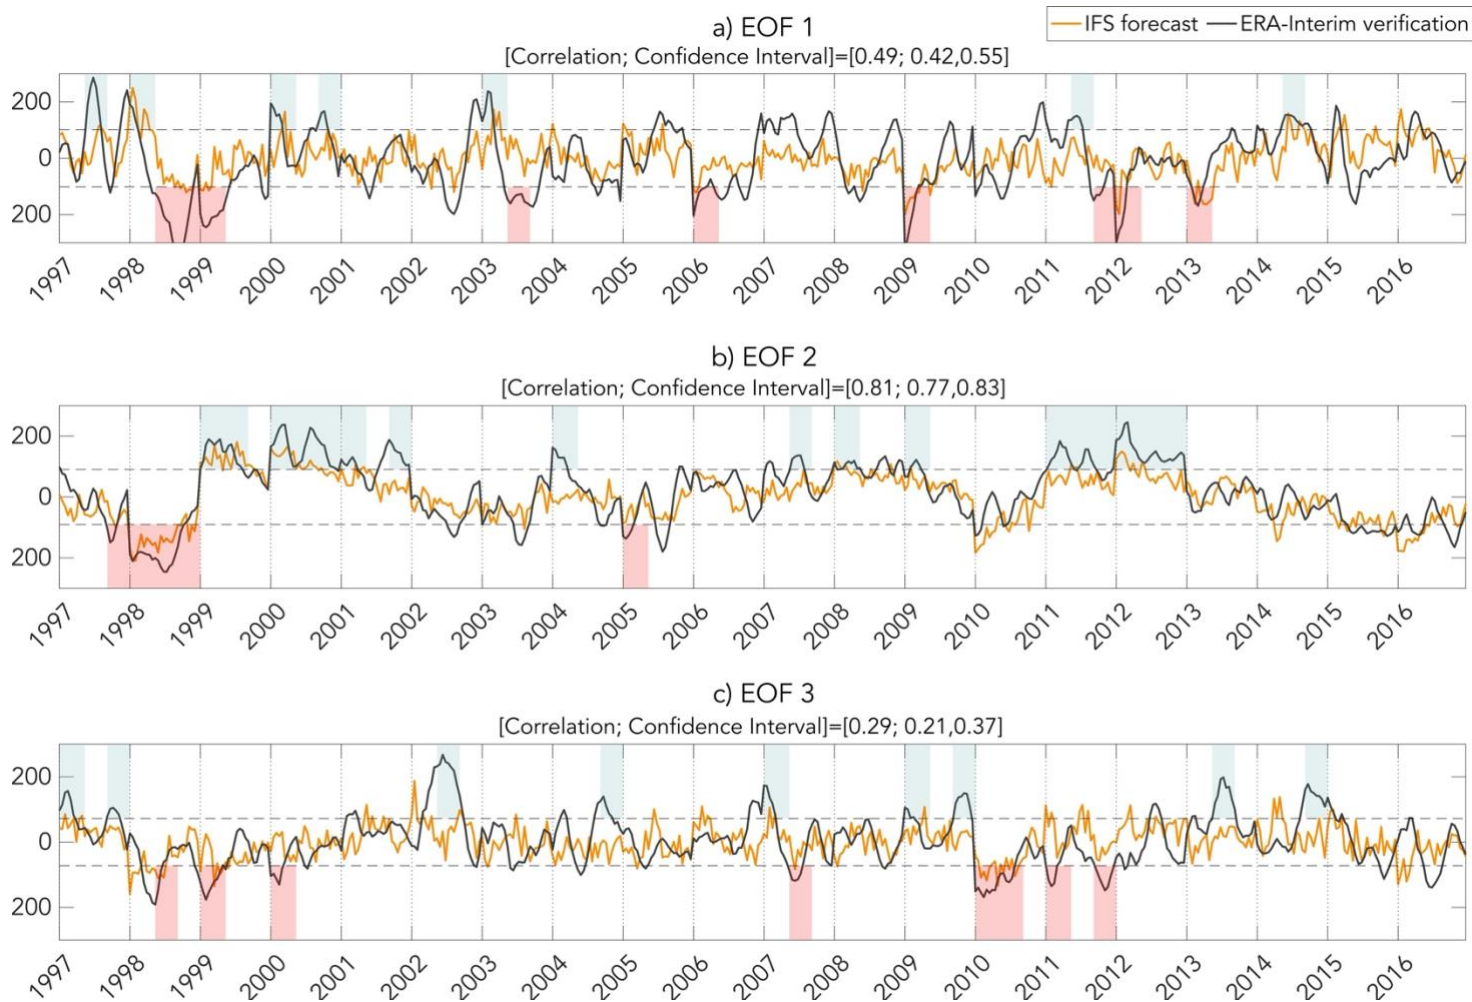

**Figure 2:** Spring (MAM, 1979-2014) zonal wind climatology (filled contours) with colored contours showing the first three EOF patterns. The variance explained by each EOF is shown in the title for each panel. Units of the zonal wind climatology are m/s. The EOF zonal wind anomaly contours span +/- 1 to 7 m/s in 2 m/s intervals.

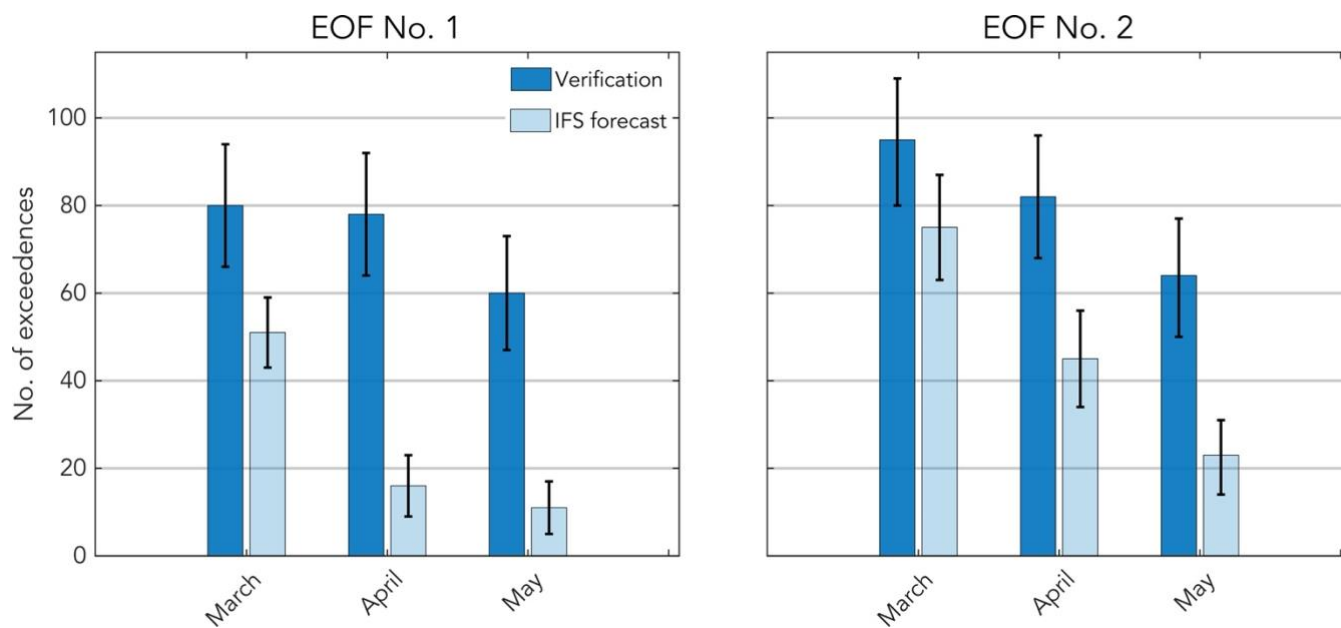

**Figure 3:** Monthly mean (MAM, 1979-2014) frequencies (filled contours) of STT to 500 hPa (top row), STT to the PBL (middle row), and TME (bottom row), for time periods when PCs 1-3 are greater than 1 STD from climatology for the negative EOF phase (units of STDs). Colored contours show the EOF patterns associated with each composite. See Supplement Fig. S2-S4 for composites of the positive EOF phase.

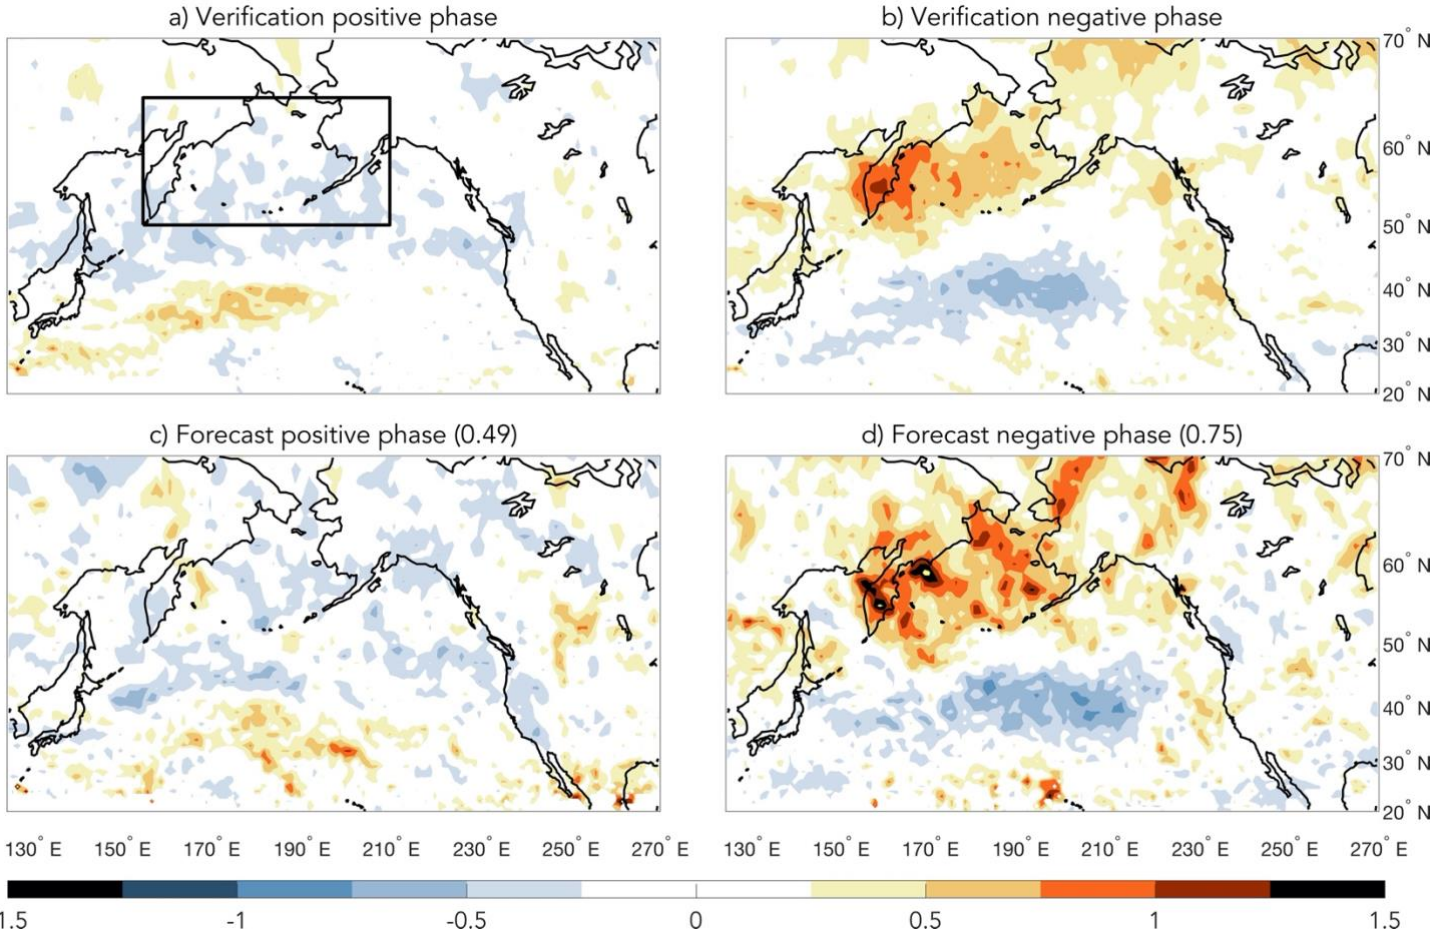

**Figure 4:** Time series of weeks 3-5 average zonal wind projected onto EOFs 1-3 for IFS forecasts (orange lines) and ERA-Interim verifications (black lines). The horizontal dashed lines denote  $\pm 0.8$  STDs from the mean of the verification time series. For reference, the light blue and red shading denote the months that were included in the monthly average composites used to create Fig. 3. Correlations between the forecasts and verifications (with 95<sup>th</sup> percentile confidence intervals) are shown in the titles of each panel.

**Figure 5:** Number of times that a weeks 3-5 average verification or forecast exceeded the 0.8 STD threshold for the 1997-2016 hindcast period (i.e., the periods in Fig. 4 where the black or orange lines, respectively, was above or below the dashed horizontal STD reference lines). 95<sup>th</sup> percentile bootstrap confidence intervals are shown as whiskers.

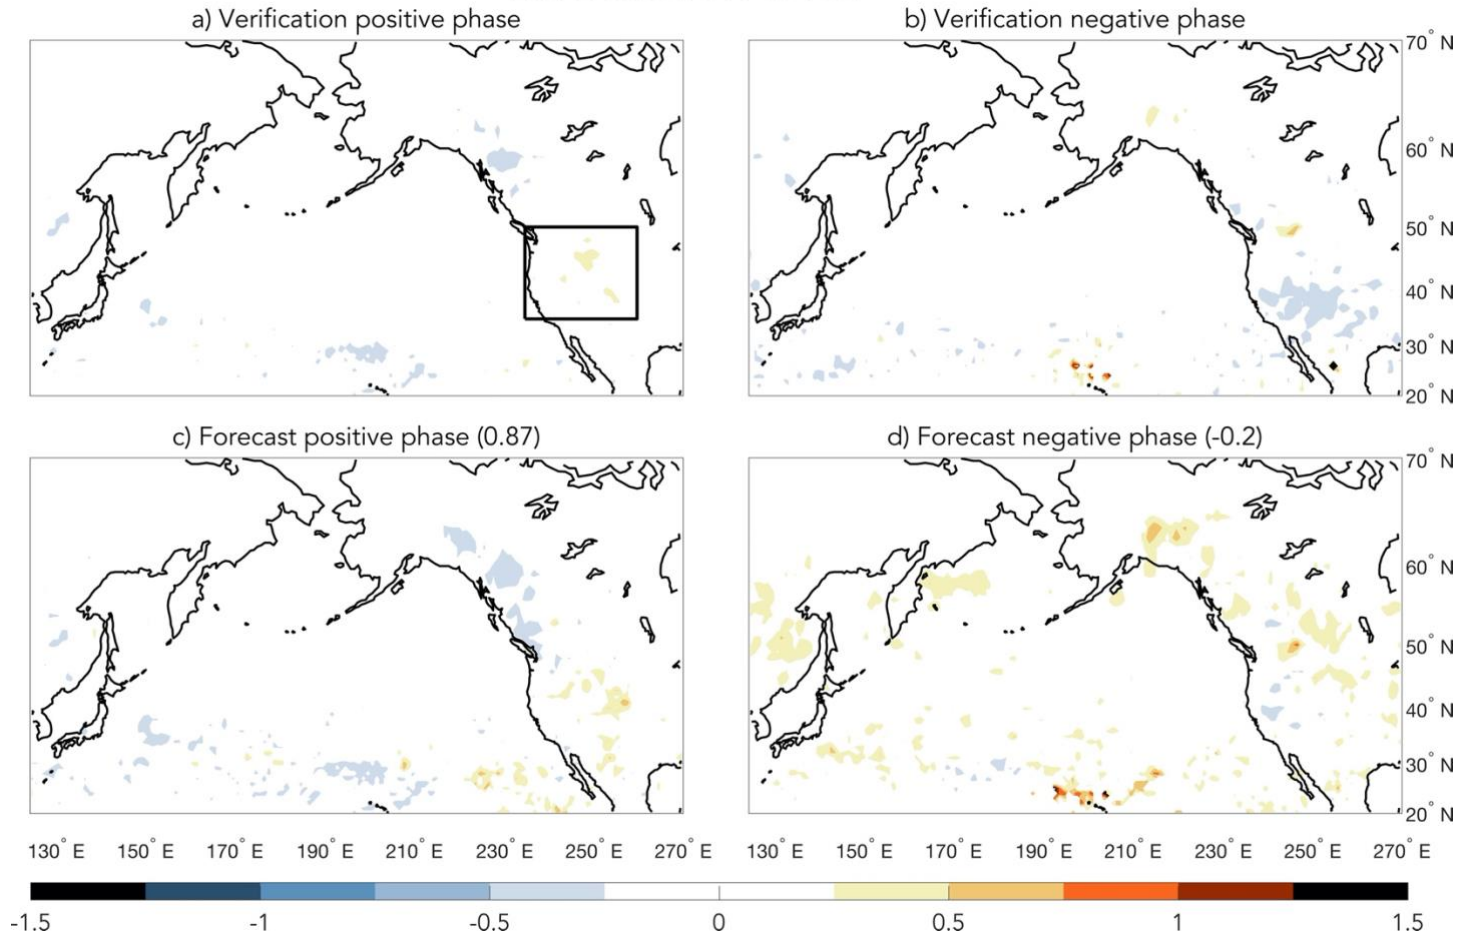

# EOF1-based STT to 500 hPa

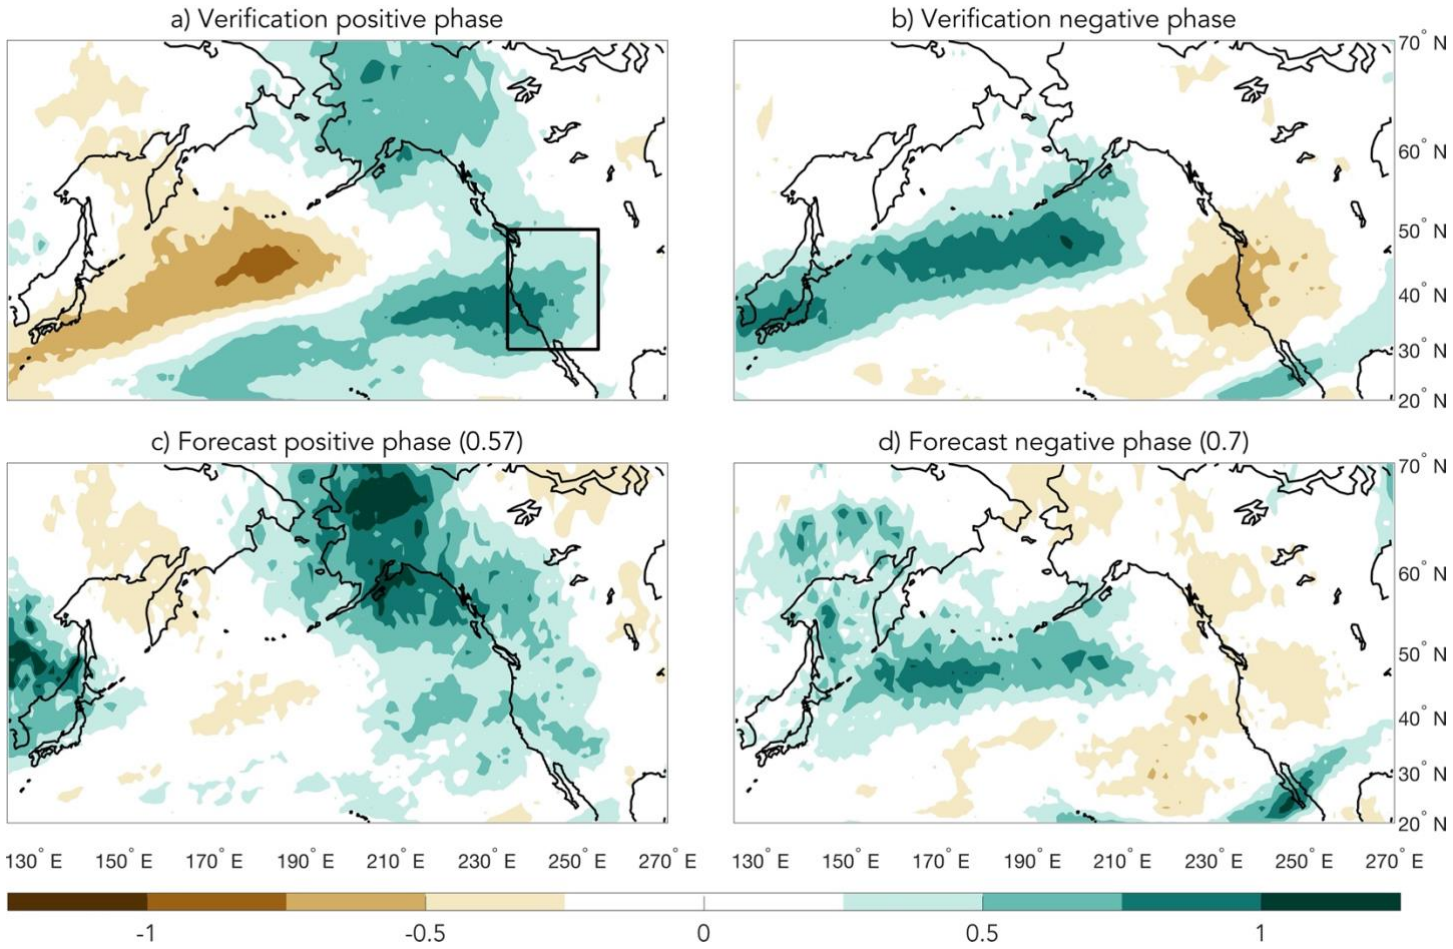

**Figure 6:** (a), (b) EOF1-based composites of STT to 500 hPa for weeks 3-5 forecast periods when the verification time series (black line in Fig. 4) was above (positive phase) or below (negative phase) the 0.8 STD threshold. (c), (d) EOF1-based composites of STT to 500 hPa for weeks 3-5 forecast periods when the forecast time series (orange line in Fig. 4) was above (positive phase) or below (negative phase) the 0.8 STD threshold. The black box outlines the North Pacific subregion used for creating the transport PDF in Fig. 10a. Units are in STDs and pattern correlations between top and bottom panels (cf., (a) versus (c) and (b) versus (d)) are shown in the bottom row titles.

# EOF2-based STT to PBL

**Figure 7:** (a), (b) EOF2-based composites of STT to the PBL for weeks 3-5 forecast periods when the verification time series (black line in Fig. 4) was above (positive phase) or below (negative phase) the 0.8 STD threshold. (c), (d) EOF2-based composites of STT to the PBL for weeks 3-5 forecast periods when the forecast time series (orange line in Fig. 4) was above (positive phase) or below (negative phase) the 0.8 STD threshold. The black box outlines the western to intermountain-western US subregion used for creating the transport PDF in Fig. 10b. Units are in STDs and pattern correlations between top and bottom panels (cf., (a) versus (c) and (b) versus (d)) are shown in the bottom row titles.

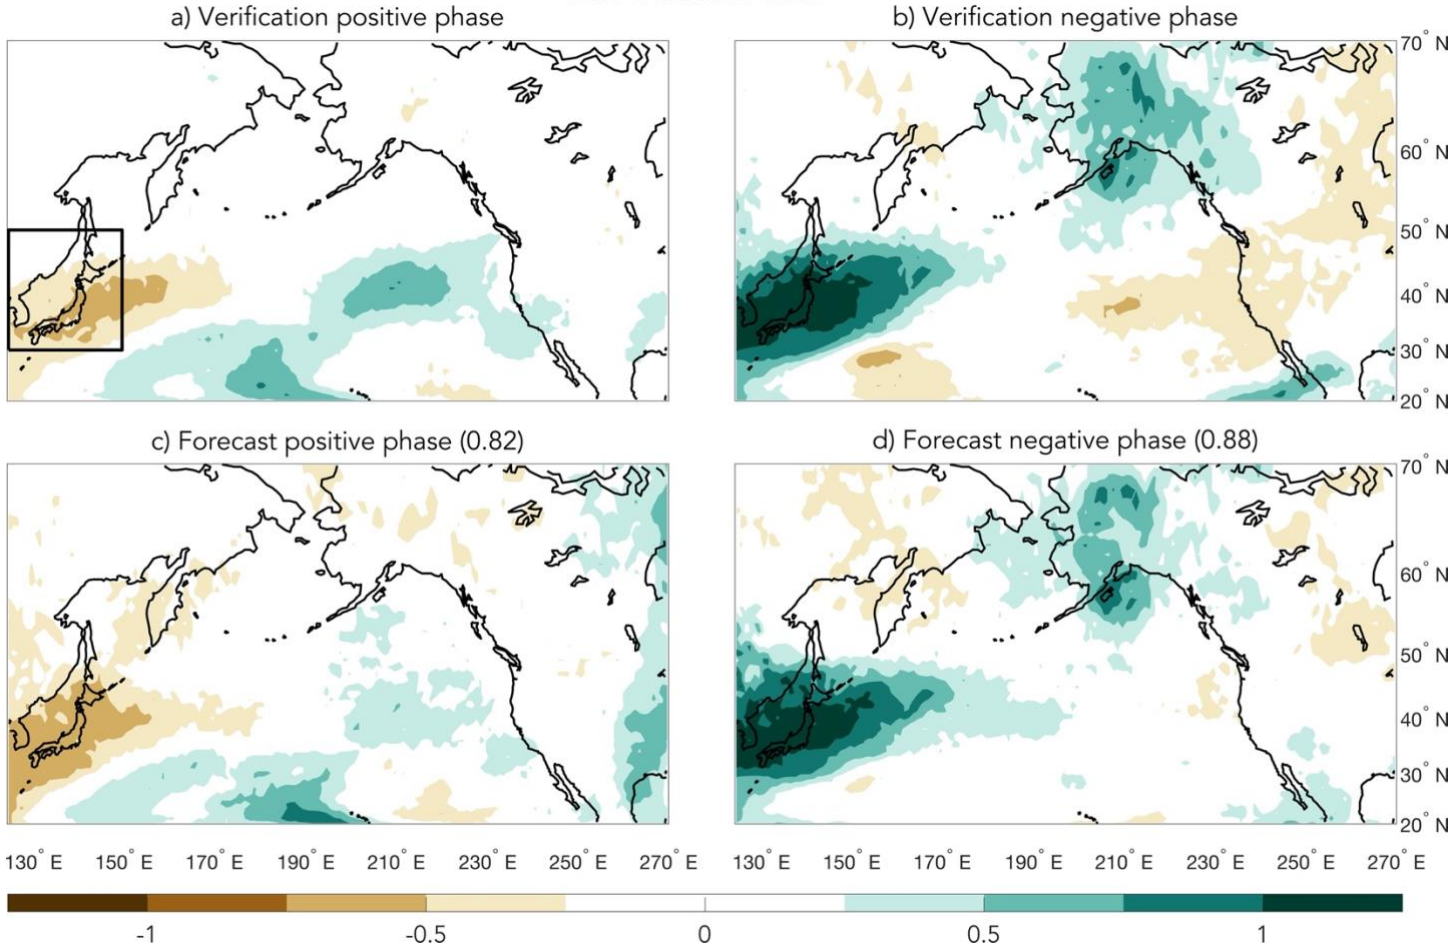

# EOF1-based TME

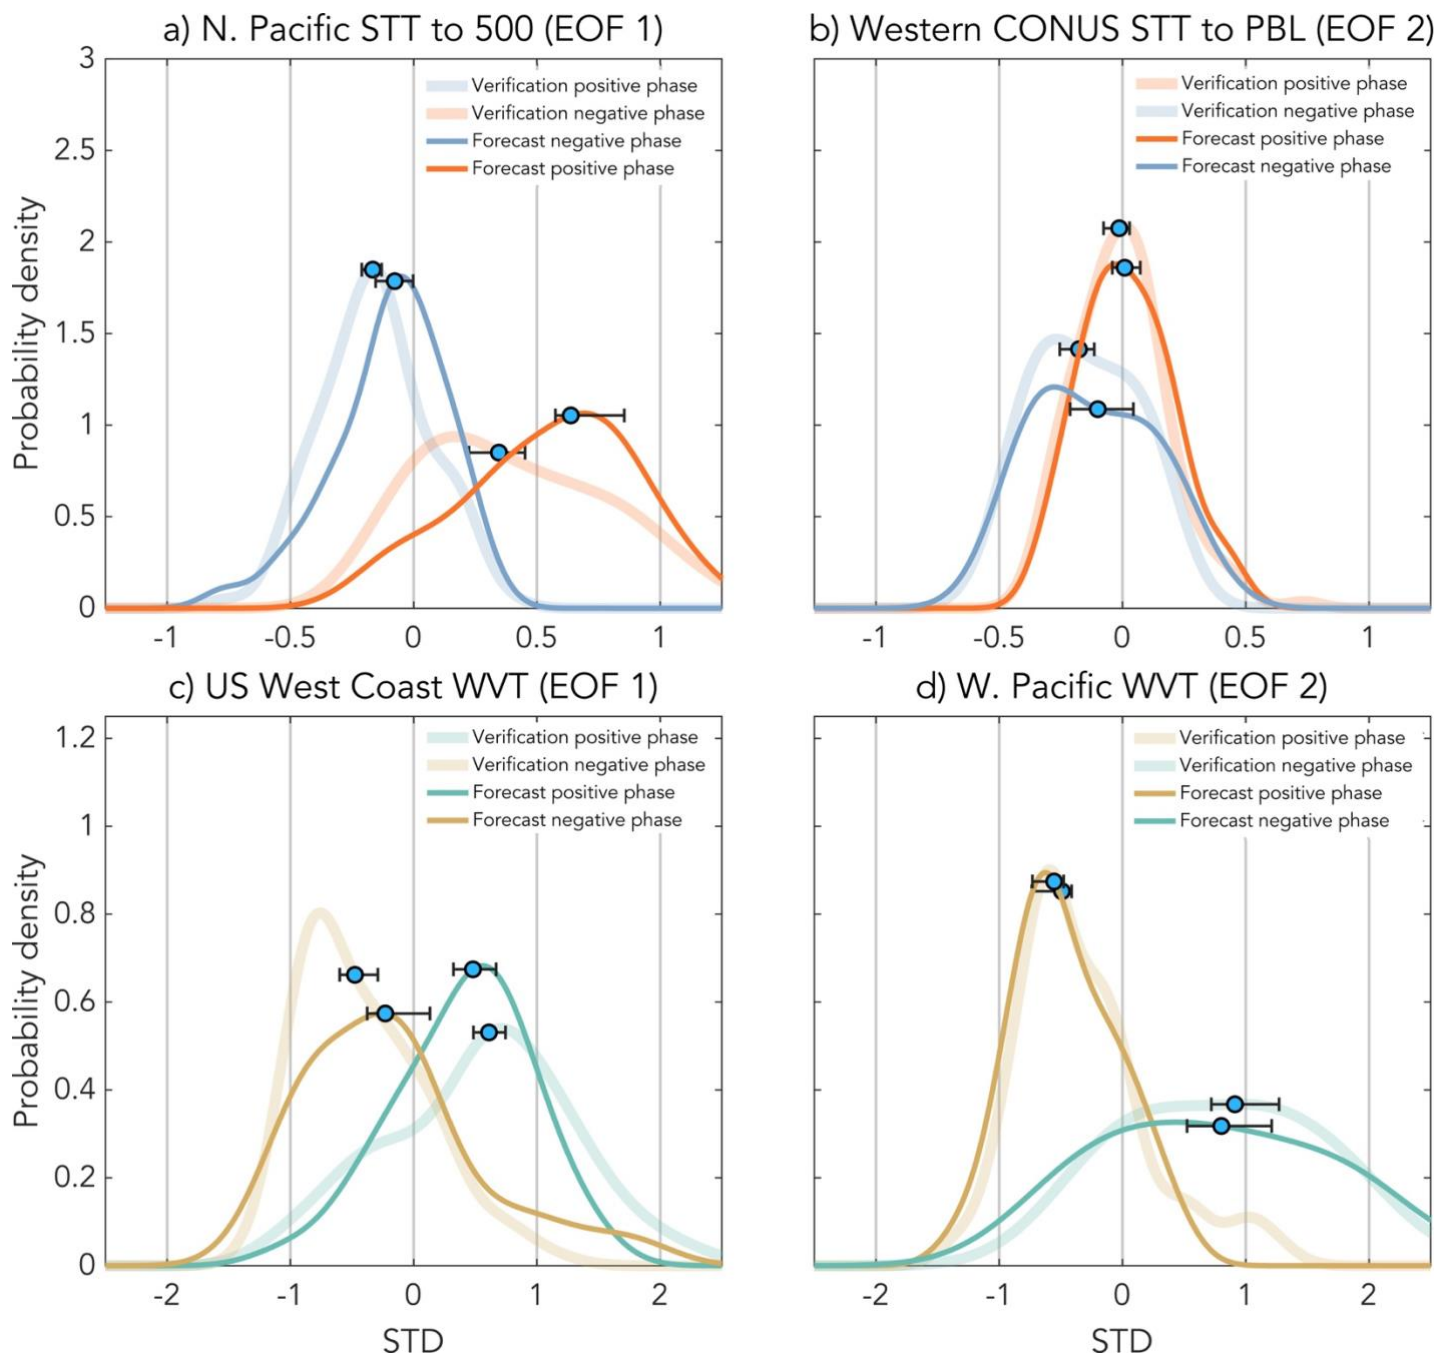

**Figure 8:** (a), (b) EOF1-based composites of TME for weeks 3-5 forecast periods when the verification time series (black line in Fig. 4) was above (positive phase) or below (negative phase) the 0.8 STD threshold. (c), (d) EOF1-based composites of TME for weeks 3-5 forecast periods when the forecast time series (orange line in Fig. 4) was above (positive phase) or below (negative phase) the 0.8 STD threshold. The black box outlines the western US subregion used for creating the transport PDF in Fig. 10c. Units are in STDs and pattern correlations between top and bottom panels (cf., (a) versus (c) and (b) versus (d)) are shown in the bottom row titles.

# EOF2-based TME

690 **Figure 9:** (a), (b) EOF2-based composites of TME for weeks 3-5 forecast periods when the verification time series (black line in Fig. 4) was above (positive phase) or below (negative phase) the 0.8 STD threshold. (c), (d) EOF2-based composites of TME for weeks 3-5 forecast periods when the forecast time series (orange line in Fig. 4) was above (positive phase) or below (negative phase) the 0.8 STD threshold. The black box outlines the West Pacific subregion used for creating the transport PDF in Fig. 10d. Units are in STDs and pattern correlations between top and bottom panels (cf., (a) versus (c) and (b) versus (d)) are shown in the bottom row titles.

**Figure 10:** Probability density functions (PDFs) of (a) EOF1-based STT to 500hPa for the North Pacific subregion, (b) EOF2-based STT to the PBL for the western to intermountain-western US subregion, (c) EOF1-based TME to the western US subregion, and (d) EOF2-based TME to the West Pacific subregion. IFS-based forecasts are shown in solid dark lines and ERA-Interim-based verifications are shown as thicker light lines; for both forecasts and verifications, medians are shown as blue dots and 95<sup>th</sup> percentile bootstrap confidence intervals are shown as whiskers. Units are in STDs.

**Figure 11:** (a) El Niño- and (b) La Niña-based monthly mean (MAM, 1979-2014) frequencies of STT to the PBL (filled contours) and zonal winds (contours) for time periods when the NOAA ONI was  $\pm 0.8$  STDs from climatology (units of STDs). Note: for correct comparison, panels (a) should be compared to panels (d) from Fig. 4; compare also panels (a) and (b) here to panels (d) and (c) from Fig. S3. (c) Probability density functions (PDFs) of EOF2-based STT to the PBL for the western to intermountain-western US subregion. (d) Time series of the NOAA ONI (blue line) and PC2 (orange line), where ONI has multiplied by -1 for ease of comparison.

710 **Appendix**

To verify that EOFs 1-3 represent distinct patterns that are robust to variations in sampling period (North et al. 1982), we conducted several calculations. To begin, a 10,000 member bootstrap ensemble of 200 hPa zonal wind EOFs was created (resampling with replacement), where each bootstrap member consisted of ‘N’ randomly selected monthly mean 200 hPa zonal wind anomalies for the Pacific basin domain shown in Fig. 2. The ‘N’ randomly selected anomalies are chosen from the pool  
715 of all MAM 1979-2016 monthly means, and N=114, which is the number of months in the original EOF calculation for MAM, 1979-2016. The resulting data was used in three calculations.

First, the pattern correlation between each bootstrap ensemble member EOF and the corresponding original EOF was calculated. The median pattern correlation for all 10,000 bootstrap ensemble members was then calculated. For all three EOFs,  
720 the median pattern correlation was near 0.9 (individual values are shown for each of the three EOFs in the title bars of Fig. A1 a-f). Next, the median of the variance explained was calculated for each bootstrap ensemble EOF. For all three EOFs, the variance explained for the original EOFs and for the median of the bootstrap ensemble EOFs is within a couple percent (individual values are shown for each of the EOFs in the title bars of Fig. A1 a-f). And finally, the standard deviation of the variance explained was calculated for each of the bootstrap ensembles (Fig. A1g). The spread (measured by the standard  
725 deviation) is small enough that there is no overlap between each of the first three EOFs. In combination, these calculations support the notion that the first three 200 hPa zonal wind EOFs are not degenerate according to the criteria outlined in North et al. 1982.

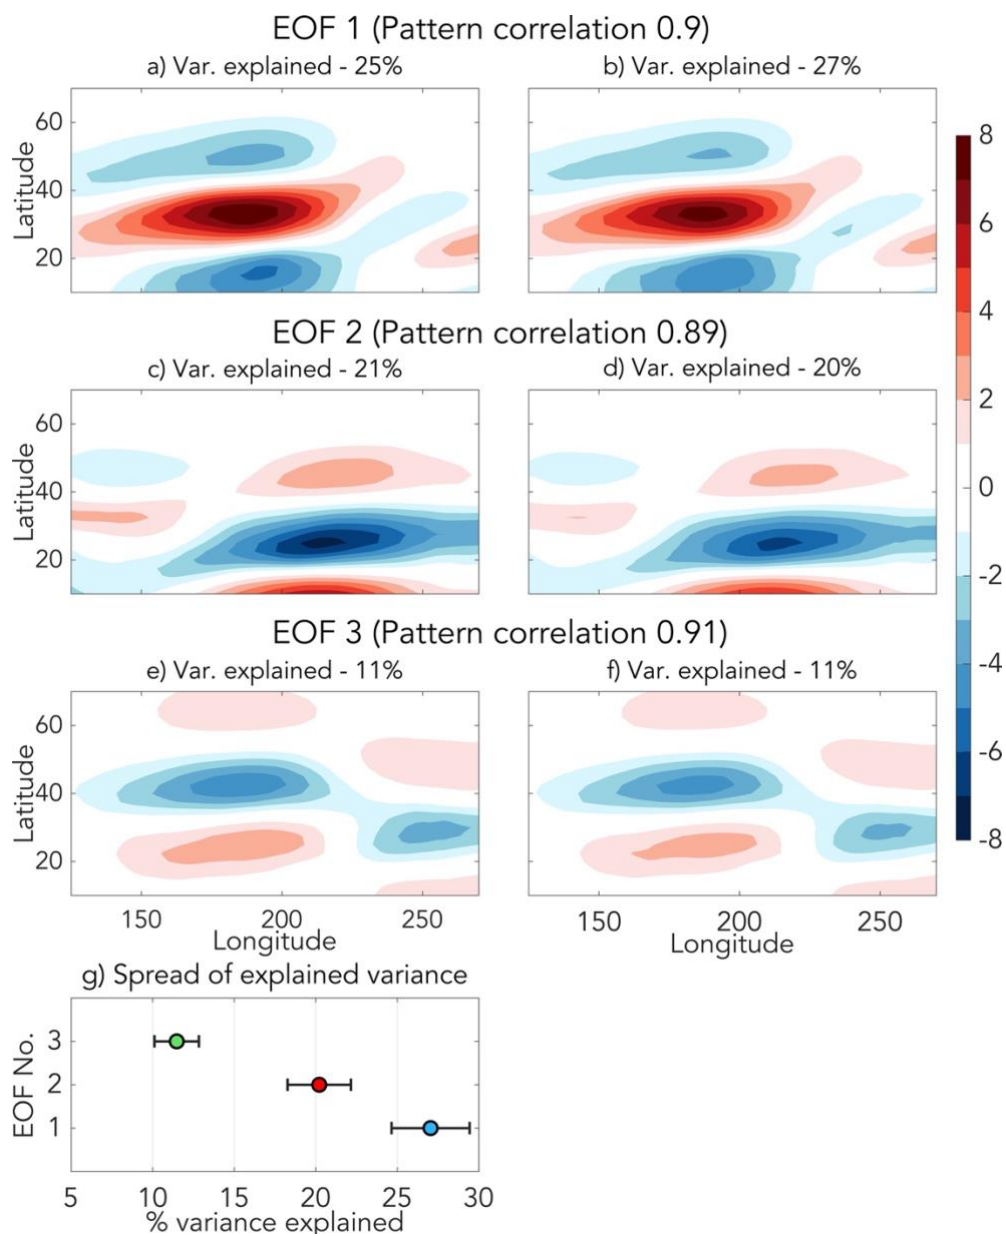

Figure A1: (a), (c), and (e) 200 hPa zonal wind EOF patterns for MAM, 1979-2016, which correspond to the EOF contours shown in Figs. 2-3 and S1-S4. (b), (d), and (f) 200 hPa zonal wind EOF patterns for the bootstrap ensembles corresponding to panels (a), (c), and (e), respectively. For each row in (a)-(f), the median pattern correlation between the original (left column) and bootstrap ensembles (right column) are shown in the subtitle. The subtitle of each panel in (a)-(f) also shows the variance explained (original EOFs, left column) or the median variance explained (bootstrap ensembles, right column) for each EOF. (g) Median variance explained for the bootstrap ensemble (solid marker), and the spread of variance explained for the bootstrap ensembles of each EOF, where the spread is calculated as 1 STD of the variance explained (shown as whiskers).
