Abstract. The effect of parameterized deep convection on warm conveyor belt (WCB) activity and jet stream is investigated by performing simulations of an explosively-developing large-scale cyclone that occurred during the North Atlantic Waveguide and Downstream Impact Experiment (NAWDEX) field campaign using the Météo-France global atmospheric model ARPEGE. Three simulations differing only from their deep convection representation are analysed. The first one was performed with the

5 Bougeault (1985) scheme (B85), the second one with the Prognostic Condensates Microphysics and Transport (PCMT) scheme of Piriou et al. (2007), and the third one without any parameterized deep convection. In the latter simulation, the release of convective instability at the resolved scales of the model generates localized cells marked by strong heating with few degrees extent in longitude and latitude along the fronts. In runs with active parameterized deep convection (B85, PCMT), the heating rate is more homogeneously distributed along fronts as the instability release happens at sub-grid scales. This difference leads

10 to more rapid and abrupt ascents in the WCB without parameterized deep convection, and more moderate but more sustained ascents with parameterized deep convection. While the number of WCB trajectories does not differ much between the three simulations, the averaged heating rates over the WCB trajectories exhibits distinct behavior. After one day of simulations, the upper-level heating rate is in average larger with B85 scheme leading to stronger potential vorticity (PV) destruction. The difference comes from the large-scale heating and not the parameterized heating. A comparison with (re)analyses and a large

15 variety of airborne observations from the NAWDEX field campaign (Doppler radar, Doppler lidar, dropsondes) made during the coordinated flights of two aircraft in the WCB outflow region shows that B85 performs better in the representation of the double jet structure at 1-day lead time than the other two simulations. That can be attributed to the more active WCB at upper levels. However this effect is too strong and that simulation becomes less realistic at longer forecast range (1.5 to 2 days) than the other ones. The simulation with PCMT scheme has an intermediate behavior between the one with B85 scheme and

20 without parameterized deep convection but its impact on the jet stream is closer to the latter one. Finally, additional numerical experiments show that main differences in the impact on the jet between PCMT and B85 largely come from the chosen closure, the former being based on CAPE and the latter on moisture convergence.

1   Introduction

Despite significant and continuous improvements of numerical weather forecasts during the last decades (Simmons and
25   Hollingsworth, 2002; Bauer et al., 2015), mid-latitude weather forecast errors still occur at synoptic and planetary scales.
For instance, at short-range (days 1-3) weather forecasts still struggle to accurately predict the intensity, timing and location
of extratropical storms (Korfe and Colle, 2018) and in particular their wind gusts footprints (Hewson et al., 2014). At medium
range (days 4-8), forecast busts may occur in the prediction of large-scale atmospheric circulation patterns like blockings
(Rodwell et al., 2013; Grams et al., 2018; Maddison et al., 2020). Forecast errors are usually characterized by an upscale and
30   downstream error growth (Zhang et al., 2007; Selz and Craig, 2015), which start at convective and mesoscale (Rodwell et al.,
2013). They, then, often propagate downstream and amplify along upper-tropospheric Rossby wave trains (Gray et al., 2014;
Lillo and Parsons, 2017) where nonlinear effects are strong (Baumgart et al., 2018). They finally form large-scale forecast error
patterns further downstream, typically at the end of storm tracks like over western Europe (Grams et al., 2018; Maddison et al.,
2020).

35   These forecast errors originate from two main sources of uncertainties: uncertainties in determining the initial state of
the atmosphere and uncertainties due to the imperfections of Numerical Weather Prediction (NWP) models (Tribbia and
Baumhefner, 1988). But it is somewhat difficult to determine the origins of forecast busts among these two sources as they
intertwine and can compensate or reinforce each other (Rodwell et al., 2013). Among the model deficiencies, the representation
of subgrid-scale physical processes (e.g., cloud microphysics, convection, radiation, turbulence) by different parametrization
40   schemes is a key question and such schemes are constantly upgraded.

The question of the impact of diabatic processes on the predictability of the atmospheric flow was central to the international
NAWDEX (North Atlantic Waveguide Downstream and impact EXperiment) project and its field campaign that occurred
in September-October 2016 (Schäfler et al., 2018). In particular, one main hypothesis of the project is that the potentially
misrepresented diabatic processes embedded in the so-called warm conveyor belts (WCBs) play a key role in triggering forecast
45   errors along the North Atlantic upper-tropospheric waveguide. They may significantly deteriorate the forecast of high-impact
weather events more downstream. WCBs correspond to air masses flowing within the boundary layer in the warm sector of
extratropical cyclones and ascending to the tropopause level east of the cyclone center (Browning, 1990; Wernli and Davies,
1997). These coherent air masses make the connections between the different layers of the troposphere as they gain moisture
in the boundary layer, undergo heat release by condensation when they ascend and have an impact on the upper-tropospheric
50   circulation. When they reach the tropopause level, negative Potential Vorticity (PV) is generated in the WCB outflow region
that reinforces the ridge downstream of the cyclone, but also the upper-tropospheric PV gradient and hence the jet stream
(Pomroy and Thorpe, 2000; Grams et al., 2011; Schemm et al., 2013; Chagnon et al., 2013; Gray et al., 2014). Uncertainties
in the heat release within WCBs due to misrepresented cloud microphysics or convection could trigger forecast errors at the
tropopause level that may then propagate downstream along the waveguide (Martinez-Alvarado et al., 2016; Grams et al., 2018;
55   Maddison et al., 2020). The objective of the present study is to investigate the effect of parameterized deep convection in a
global NWP model on the WCB activity and the jet stream.

Embedded convective activity within WCBs has been initially identified using airborne and satellite-derived data within an extratropical cyclone during the Experiment on Rapidly Intensifying Cyclones over the Atlantic (ERICA) field experiment (Neiman et al., 1993). Various ground-based, spaceborne and airborne remote sensing measurements confirm the regular presence of convective activity in the warm sector of extratropical cyclones and WCBs in particular (Crespo and Posselt, 2016; Flaounas et al., 2016, 2018; Oertel et al., 2019; Blanchard et al., 2020; Jeyaratnam et al., 2020). This was detected in various regions of the Northern Hemisphere; over the United States (Jeyaratnam et al., 2020), the North Atlantic ocean (Crespo and Posselt, 2016; Oertel et al., 2019, 2020, 2021; Blanchard et al., 2020, 2021) and in the Mediterranean sector (Flaounas et al., 2016, 2018). Recent numerical studies relying on convection-permitting model simulations of various extratropical cyclones also highlighted the presence of embedded convection within WCBs (Rasp et al., 2016; Oertel et al., 2019, 2020, 2021; Blanchard et al., 2020, 2021). The emerging picture is that WCBs are composed of various ascending air streams in which convective ascents may intermittently happen within the main slantwise ascending airflow. Such an intermittent convective activity may have non negligible effects on the upper-level jet stream. Oertel et al. (2020) and Blanchard et al. (2021) showed that the WCB-embedded convective cells form dipolar PV anomalies with the negative pole being closer to the jet which tend to reinforce the PV gradient and hence the jet.

Because WCB-embedded convection plays an important role in the large-scale circulation, it is worth investigating the effect of parameterized deep convection on WCBs in models that do not have enough resolution to explicitly resolved that phenomenon. The contribution of parameterized convection in the total heating and precipitation rates within extratropical cyclones varies a lot by changing schemes as shown by Martinez-Alvarado et al. (2014b) and Booth et al. (2018). Differences in total precipitation rates between models usually vary much less than differences in the contribution of parameterized convection to the total. Done et al. (2006) showed that the upper-level large-scale circulation is sensitive to the relative amount of parameterized vs explicit convection but their focus was on the effect of mesoscale convective systems and not WCBs of deep cyclones. More relevant to the present study, the impact of convection parametrization on WCB dynamics and its effect on the upper-level flow has been studied by Martinez-Alvarado and Plant (2014) in a case-study of a North Atlantic extratropical cyclone. The authors show that parameterized convection "regulates the action of large-scale heating" by releasing convective instability at sub-grid scales which would have otherwise been released at larger and resolved scales. Because of this regulation, WCB trajectories more gradually ascend when parameterized convection is more active than when it is reduced. Furthermore, in presence of reduced parameterized convection, the more abrupt ascents lead to more important impact on upper level circulation even though differences with active parameterized convection are small at 24-hour lead time (Martinez-Alvarado et al., 2014a). In the same vein, the present study aims at addressing the following questions

– How different are WCBs between simulations with active parameterized deep convection and those without ?

– What is the impact of parameterized deep convection on the jet stream at short range (less than 2 days) ?

– How different are WCBs and their impact on the jet stream between simulations performed with distinct deep convection schemes ?

90   Our approach is based on the case study of an extratropical cyclone that occurred during NAWDEX called the Stalactite cyclone (29 September - 3 October 2016) and corresponding to Intensive Observing Period (IOP) 6. It was an explosively deepening cyclone at a rate of roughly 24 hPa in 24 hours (Flack et al., 2021) that formed off the east coast of Newfoundland and travelled over the North Atlantic toward Iceland and Greenland. This large-scale cyclone participated in the formation of a blocking over Scandinavia (Schäfler et al., 2018). The Stalactite cyclone was already the subject of several studies. Maddison
95   et al. (2019, 2020) showed that the low predictability of the block onset at medium range was associated to uncertainties in the timing, location and intensity of that cyclone. Blanchard et al. (2020) and Blanchard et al. (2021) studied the WCB-embedded convection by performing convection-permitting model simulations while Mazoyer et al. (2021) analyzed the impact of cloud microphysics on the WCB activity of the Stalactite cyclone with similar convection-permitting simulations. Flack et al. (2021) analyzed the whole life cycle of the cyclone in simulations of two climate models. Maddison et al. (2020) showed that medium-
100 range forecast skills of the cyclone are sensitive to the choice of the deep convection schemes but none of these studies systematically investigated the role of parameterized deep convection on the WCB of the cyclone at short range. In addition to its dynamical interest, the Stalactite cyclone is worth studying because numerical simulations can be compared and validated against airborne observations: two flights of the French Falcon 20 from the Service des Avions Français Instrumentés pour la Recherche en Environnement (SAFIRE) and one flight from the Deutsches Zentrum für Luft- und Raumfahrt (DLR) Dassault
105 Falcon were conducted on 2 October 2016.

The paper is structured as follows. Section 2 is dedicated to the method. The global atmospheric model and the three numerical simulations are presented. Two of them are run with two distinct deep convection schemes while the third one has its deep convection scheme turned off. The Lagrangian trajectory algorithm, PV diagnostics, together with the reanalysis and airborne observations datasets are also summarized in section 2. In section 3, the impact of deep convection schemes on
110 heating rates and WCB trajectories is analyzed while section 4 is focused on their effect on the upper-level circulation and the jet stream. Finally, section 5 provides concluding remarks.

2   Data and method

2.1   Model and simulations set-up

The Météo-France global forecast model ARPEGE (Action de Recherche Petite Echelle Grande Echelle Courtier et al., 1991)
115 is used at a T798 resolution with full physics and 90 vertical levels. The stretched horizontal grid (mapping factor of 2.4) corresponds to about 10 km horizontal resolution over France, 15 km near Iceland and 60 km on the opposite side of the globe relative to France. The temporal resolution is 7.5 minutes. Simulations analysed in the present study are based on the 2016 operational version of the ensemble prediction system (EPS) of ARPEGE called the Prévision d'Ensemble ARPEGE (PEARP; Descamps et al., 2015) and documented in Ponzano et al. (2020) (see their table 1). Ten members that have the
120 same initial state, that is the ARPEGE operational analysis made with a 4D-Var data assimilation scheme, are considered. They only differ in the representation of at least one of the following physical package: deep convection, turbulence, shallow convection and surface oceanic fluxes. Two largely distinct deep convection schemes are used, one is the scheme developed by

Bougeault (1985), hereafter called B85, the other one is the Prognostic Condensates Microphysics and Transport scheme of Piriou et al. (2007), hereafter called PCMT. For some members, modified versions of B85 are activated. Two turbulent schemes

125 are used: the Turbulent Kinetic Energy Scheme of Cuxart et al. (2000) and the turbulence scheme of Louis (1979). Four shallow convection schemes are considered: the mass flux scheme of Kain and Fritsch (1993) and Bechtold et al. (2001), PCMT, the eddy diffusivity and Kain–Fritsch scheme, and the Pergaud et al. (2009)'s scheme. Surface oceanic fluxes are represented by the Belamari (2005)'s scheme or by an alternate version in which the evaporative fluxes are enhanced. The paper is focused on two particular members of this EPS, corresponding to the REF member and 7th member respectively of table 1 of Ponzano et al.

130 (2020). They only differ in the representation of deep convection, one using the B85 scheme and the other the PCMT scheme. The two simulations share the same physical parameterizations for turbulence (Turbulent Kinetic Energy Scheme; Cuxart et al., 2000), shallow convection (Kain and Fritsch, 1993; Bechtold et al., 2001), large-scale microphysics (Lopez, 2002) and oceanic flux (Exchange Coefficients from Unified Multi-campaigns Estimates; Belamari, 2005). Finally, a third simulation is performed without any active deep convection scheme (hereafter called NoConv) but with the same other physical packages as the other

135 two simulations and will serve as a reference to assess the impact of B85 and PCMT schemes.

The three simulations are hereafter systematically compared. The starting date is 12 UTC 1 October 2016 when the surface cyclone is already in its mature stage and located in the middle of the North Atlantic (see sea level pressure in Fig. 1).

2.1.1 The Bougeault (1985) deep convection scheme

This mass-flux scheme is triggered when the resolved plus subgrid-scale moisture convergence is positive in the low levels

140 and the atmospheric profile is unstable. So the scheme is closed with moisture convergence. Following Kuo (1965) the total moisture convergence is either detrained in the convective environment or precipitated. This scheme was further developed by Ducrocq and Bougeault (1995) for downdrafts. It is part of the global operational NWP (Numerical Weather Prediction) system at Météo France and is currently used to perform high-resolution deterministic operational simulations.

2.1.2 The Prognostic Condensates Microphysics and Transport scheme (Piriou et al., 2007)

145 This convection scheme separates microphysics and transport in grid-scale equations to overcome stationary cloud budget assumptions, as proposed by Piriou et al. (2007). Liquid and ice cloud condensates, as well as rain and snow have prognostic mixing ratios, to deal with the same level of sophistication inside convective updraft as in the resolved-scale microphysics (Lopez, 2002; Bouteloup et al., 2011), therefore including autoconversion, aggregation, collection, riming, melting, etc. The closure of all experiments run with PCMT in the present study is based on CAPE (Convective Available Potential Energy). As

150 previously said, this scheme is used in PEARP but also is part of the CNRM Earth System Model for CMIP6 (Roehrig et al., 2020).

2.2 Model output and diagnostics

The output datasets of the simulations are provided on a regular longitude-latitude grid of $0.5°$, a pressure grid spacing of 50 hPa in the vertical and a frequency of 15 minutes.

155 2.2.1 WCB trajectories

The Lagrangian trajectory code is designed to work with latitude $\times$ longitude $\times$ pressure files of zonal wind u, meridional wind v, vertical velocity ω and other variables such as temperature and diabatic tendencies. The algorithm is based on a prediction-correction method of the advection at the midpoint of the trajectory. Let DT be the time interval between two model outputs. To account for curvature effects, the trajectory model has higher resolution than the model outputs and its time

160 step dt is such as $n \times dt = DT$. At $t = i \times DT + j \times dt$ (where $j = 1, ..., n$) and for each point $(x(t), y(t), p(t))$ (p denotes pressure, x and y are horizontal coordinates) belonging to a trajectory we look for the previous position $(x(t-dt), y(t-dt), p(t-dt))$, the advection being made with u, v and ω in the middle of the trajectory portion at $t-dt/2$ which is not known a priori. We first apply a time interpolation to compute the 3D wind field at time t using the two closest model outputs for (u, v, ω) at time $i \times DT$ and $(i+1) \times DT$ and referred to as $\mathbf{U}(x, y, p, t)$. We then apply an iterative method starting with the

165 wind at the point of the trajectory at time t (i.e $\mathbf{U}(x(t), y(t), p(t))$) to build up a first estimation of the previous position of the trajectory $(x_1(t-dt), y_1(t-dt), p_1(t-dt))$ and extract the wind along this first estimated trajectory at $t-dt/2$ (called $\mathbf{U_1}(x(t-dt/2), y(t-dt/2), p(t-dt/2))$ by horizontal, vertical and time interpolation. Horizontal interpolation is bilinear (4 neighbouring points are used). A second estimated trajectory is calculated using $\mathbf{U_1}$ leading to a second estimation of the previous position $(x_2(t-dt), y_2(t-dt), p_2(t-dt))$. The process can be repeated several times but practical tests show it

170 converges after about 2 iterations. If a trajectory goes beyond 975 hPa, its position is shifted to 975 hPa. Note that such an algorithm allows the computation of both backward and forward trajectories. In what follows, DT and dt are equal to 15 and 7.5 minutes respectively ($n = 2$).

Forward trajectories are initialized at 12 UTC 1 October in the warm sector of the extratropical cyclone and computed during 48 hours. To select WCB trajectories, a criterion of ascent exceeding 300 hPa within 1 day during the period between 12 UTC

175 1 October and 12 UTC 3 October is applied. This is a less strict criterion than the more usual criterion of 600 hPa ascent within 2 days (Madonna et al., 2014; Binder et al., 2016) but allows a broad view of the different ascents in the WCB.

2.2.2 Heating and PV tendencies

The Ertel potential vorticity q and its Lagrangian derivative can be expressed as (Ertel, 1942):

$$q \quad = \quad \frac{1}{\rho}\zeta_{\mathbf{a}} \cdot \nabla\theta, \tag{1}$$

180
$$\frac{Dq}{Dt} \quad = \quad \frac{1}{\rho}\left(\zeta_{\mathbf{a}} \cdot \nabla\dot{\theta} + \nabla \times \mathbf{F} \cdot \nabla\theta\right), \tag{2}$$

where $D/Dt = \partial/\partial t + u\partial/\partial x + v\partial/\partial y + \omega\partial/\partial p$ is the Lagrangian derivative, θ the potential temperature, ρ is density, $\zeta_{\mathbf{a}}$ the three-dimensional absolute vorticity vector, ∇ the three-dimensional gradient and $\mathbf{F}$ the three-dimensional frictional acceler-

ation. The diabatic heating is denoted as $\dot{\theta} = D\theta/Dt$. These two equations can be rewritten under the hydrostatic balance in pressure coordinates as:

$$q = -g\left[(\zeta + f)\frac{\partial \theta}{\partial p} + \frac{\partial u}{\partial p}\frac{\partial \theta}{\partial y} - \frac{\partial v}{\partial p}\frac{\partial \theta}{\partial x}\right], \tag{3}$$

$$\frac{Dq}{Dt} = -g\left[(\zeta + f)\frac{\partial \dot{\theta}}{\partial p} + \frac{\partial u}{\partial p}\frac{\partial \dot{\theta}}{\partial y} - \frac{\partial v}{\partial p}\frac{\partial \dot{\theta}}{\partial x} + \left(\frac{\partial F_y}{\partial x} - \frac{\partial F_x}{\partial y}\right)\frac{\partial \theta}{\partial p} + \frac{\partial F_x}{\partial p}\frac{\partial \theta}{\partial y} - \frac{\partial F_y}{\partial p}\frac{\partial \theta}{\partial x}\right], \tag{4}$$

where F_x and F_y are the zonal and meridional components of the frictional acceleration. Even though the friction-induced PV tendency is not negligible and generally generates a positive PV anomaly in lower troposphere (Stoelinga, 1996), it is not shown in the present study which is focused on the upper-level PV modification. PV modification along WCB has been generally attributed to the term involving the vertical gradient of the diabatic heating (Wernli and Davies, 1997; Joos and Wernli, 2012), that is the first term on the right-hand-side of Eq.(4). The second and third terms involving the horizontal gradient of the heating has been generally considered as a second-order effect. Very recently the horizontal gradient has been shown to be very important in high-resolution convection-resolving simulations (Oertel et al., 2020).

The first method to compute the diabatic heating $\dot{\theta}$ consists of approximating the time and space derivatives of potential temperature by centred finite-difference schemes. An alternative to compute the total heating is to sum all the temperature tendencies due to each physical process (large-scale heating, parameterized heating, radiation, turbulence) that are made available as model outputs on a non regular grid. Spatial interpolations were necessary to get them on the same regular $0.5° \times 0.5°$ grid of the model outputs. The total heating obtained with this second method was found to be less accurate to represent the change in potential temperature undergone by the Lagrangian trajectories. Hence the first method based on centred finite-differences schemes is used to make all the main figures of the paper. The second method is only used in some supplementary figures to show the robustness of the results as well as to attribute the total heating to some specific physical processes, which cannot be provided by the first method. Finally, to get the PV tendencies due to the heating (first three terms on the rhs of Eq. (4)), centred finite-difference schemes are applied to the heating.

2.3 Reanalysis and observations

2.3.1 Reanalysis and operational analysis

Operational analyses from ARPEGE and the Integrated Forecasting System (IFS) of the European Centre for Medium-Range Weather Forecasts (ECMWF) are used on the same regular latitude-longitude grid with $0.5°$ resolution and the same pressure levels with 50-hPa spacing as the model simulations outputs. ERA5 reanalysis datasets (Hersbach et al., 2020) are also used with the same $0.5°$ grid spacing, that is keeping one grid point every two grid points from the $0.25°$ original grid of the reanalysis.

2.3.2 Airborne observations and comparison to model outputs

Two coordinated flights of the SAFIRE and DLR Falcon aircrafts were conducted from 09 UTC to 12 UTC 2 October between Iceland and Greenland to sample the WCB outflow region of the Stalactite Cyclone. The two aircraft followed each other with

a 10-minutes interval between 0900 UTC and 1015 UTC. The 95 GHz Doppler cloud radar RASTA (Radar Airborne System; Delanoe et al., 2013) on board the SAFIRE Falcon measured both reflectivity and Doppler velocity along three antennas

215 (nadir, backward and transverse) that allow for reconstructing the three wind components. The temporal resolution between two consecutive nadir measurements being 750 ms and the typical Falcon 20 speed 200 m s^{-1}, the horizontal resolution is near 300 m. Additional wind measurements were made during the flight of the SAFIRE Falcon by launching nine dropsondes and by in-situ sensors at the aircraft level. The 2-μm scanning coherent/heterodyne detection Doppler Wind Lidar (DWL; Weissmann et al., 2005; Witschas et al., 2017) on board the DLR Falcon measured vertical profiles of line-of-sight wind speed, horizontal

220 wind vectors, and detected aerosol/cloud layers.

Since the model output grid is $0.5° \times 0.5°$, which corresponds to 28 km $\times$ 55 km spacing in longitude and latitude respectively, the radar RASTA and DWL wind measurements are averaged over intervals of 180 s to get the same horizontal resolution as the model outputs (the Falcon travels a distance of 36 km in 180 s).

3 Impact of convection representation on heating rates and warm conveyor belt trajectories

225 ### 3.1 General overview

This subsection is dedicated to presenting differences in the main characteristics of the WCB between the three runs. The number of trajectories satisfying the WCB criterion of the present study (ascent rate of at least 300 hPa in 24 hours) does not differ much between the three runs: 9876, 10086, and 11421 for B85, PCMT and NoConv simulations respectively. The WCB trajectories share many common features between the runs. A majority of trajectories exhibit a well-marked cyclonic curvature

230 during their ascents to the east of the surface cyclone and then change their curvature in the upper troposphere over Greenland to become more zonally oriented and slightly anticyclonically curved toward Scandinavia (Fig. 1). These trajectories in the upper troposphere span a larger latitudinal band in NoConv than PCMT and B85 (compare the banded areas formed by the blue segments of the trajectories). The largest difference between the three runs concerns another set of trajectories that has a more zonal orientation from the mid-Atlantic to Western Europe near 45°N. There are very few such trajectories in B85 run,

235 while they are more abundant in PCMT and very numerous in NoConv run.

Figure 2 presents averaged quantities along the WCB trajectories of the three runs. The mean pressure is about 894 hPa at 12 UTC 1 October for the 3 runs and reaches 415 hPa for B85, 427 hPa for PCMT and 435 hPa for NoConv at 12 UTC 3 October. Some differences also appear in the 90th percentile with the WCB trajectories of the B85 run having systematically lower pressure levels than the other two runs (Fig. 2a). There are not so many differences between the mean potential temperatures

240 of the three runs. The only notable difference is the slightly higher mean temperature in the B85 run than in the other two runs from 12 UTC 2 October to 12 UTC 3 October (Fig. 2b). The time evolution of the PV along WCB trajectories is characterized by an increase followed by a decrease (Fig. 2c) which is a classical picture of WCB as they undergo PV production at low levels below the heating layer and PV destruction at upper levels above the heating (e.g. Wernli and Davies, 1997; Schemm et al., 2013). Differences in PV between the three runs are more important than differences in pressure or potential temperature.

245 Trajectories of B85 and PCMT runs undergo more important increase and decrease of PV than those of NoConv run in average.
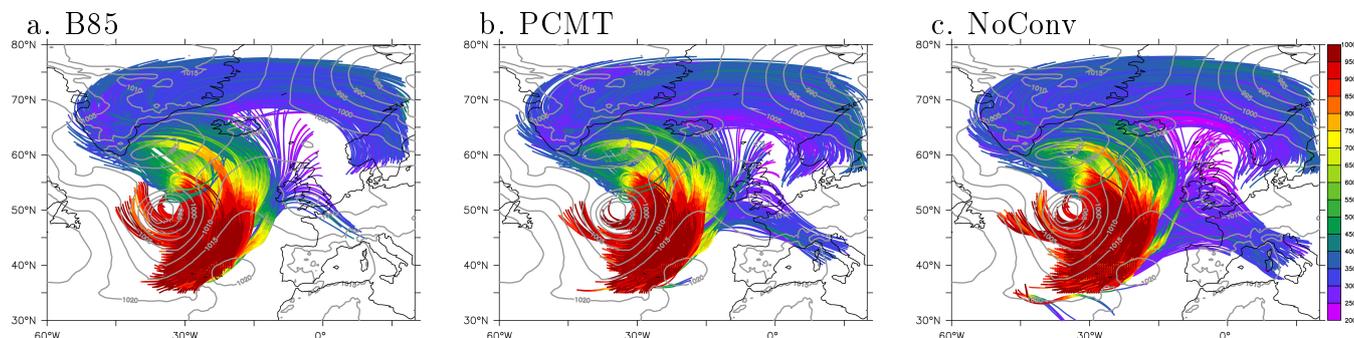

Figure 1. WCB trajectories from 12 UTC 1 October to 12 UTC 3 October coloured according to pressure (in hPa) for (a) B85, (b) PCMT and (c) NoConv simulations. The sea level pressure at 12 UTC 1 October is shown in grey contours (int: 5 hPa). Only WCB trajectories with an ascent criterion of at least 600 hPa in 48 hours are shown for clarity purposes.

While the two runs with activated parameterized convection exhibit similar increase in PV during the first 24 hours, they differ in the subsequent decrease in PV. B85 trajectories exhibit a more rapid decrease in PV between 18 UTC 2 October and 00 UTC 3 October while PCMT trajectories show smoother decrease in PV.

To get a better insight on the heating and PV evolution along trajectories, Fig. 3 shows the time evolution of the mean vertical profile of the heating and PV tendency due to the vertical gradient of the heating along WCB trajectories. While the magnitudes of the heating and PV tendency are rather similar between the three runs, some significant differences also appear. The NoConv case exhibits the strongest heating values at early stage (18 UTC 1 October) but the lowest ones at later stage (18 UTC 2 October to 06 UTC 3 October) compared to the other two cases, suggesting a more rapid destabilization of the atmosphere in NoConv. In terms of PV, the expected picture of PV gain and loss below and above the main heating layer respectively is visible for the three cases. We observe that the PV gain region presents two peaks between 12 UTC 1 October and 12 UTC 2 October, one in the boundary layer and another near 700-800 hPa. But more importantly, the negative PV tendency above the heating layer is stronger for B85 than PCMT and NoConv during the whole period and in particular between 18 UTC 2 October and 00 UTC 3 October when WCB trajectories reach these upper levels. Such a difference is also seen by computing the total PV tendency due to the heating, i.e by summing the first three terms on the rhs of Eq. (4) (not shown) and is in agreement with the more rapid decrease in PV seen in Fig. 2c for B85. This difference is mainly due to the fact that the heating reaches higher values in the upper troposphere between 2 and 3 October in B85 and thus has stronger vertical gradients (e.g., see the more important tightening of black contours between 18 UTC 2 October and 00 UTC 3 October in Fig. 3a than Figs. 3b,c).

Let us now document differences in the ascending motion of the trajectories between the three runs. The number of trajectories ascending by more than 100 hPa, 50 hPa and 25 hPa in 2 hours are indicated in Fig. 2d as function of time. NoConv has the largest number of trajectories ascending most rapidly (i.e 100 hPa within 2 hours and 50 hPa within 2 hours), B85 is the run having the lowest number while PCMT is in between whatever the time. In the category of more modest ascents (25 hPa in 2 hours), B85 and NoConv have equivalent numbers of trajectories except from 12 UTC to 18 UTC 2 October during which B85 trajectories are more numerous. During that time interval, PCMT has less WCB trajectories in that category. Beyond 18 UTC 2
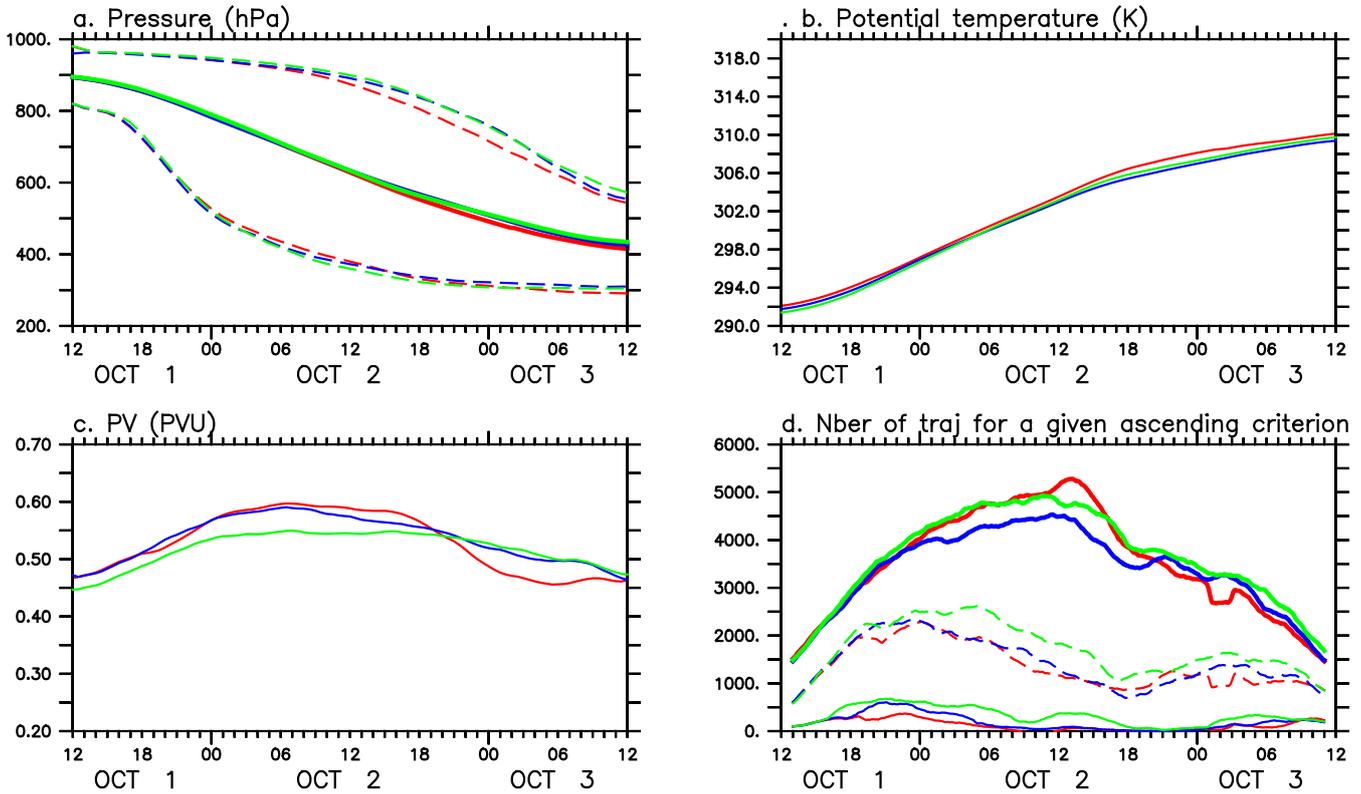

Figure 2. Time evolution along WCB trajectories of (a) mean pressure (solid lines, units: hPa) and 10th and 90th percentiles of pressure (dashed lines), (b) mean potential temperature (solid lines; units: K), (c) mean PV (units: PVU). Panel (d) indicates the number of WCB trajectories satisfying a given ascending criterion at a given time: 100 hPa in 2 hours (light solid lines), 50 hPa in 2 hours (dashed lines) and 25 hPa in 2 hours (bold solid lines). The red, blue and green curves correspond to B85, PCMT and NoConv simulations respectively.

October, the three curves do not distinguish so much from each other. These differences in the ascending motion properties are

270 synthetised in Fig. 4. The NoConv trajectories undergo the most rapid vertical motion with a maximum vertical displacement of 100 hPa in 2 hours when averaged over all trajectories. In comparison, the averaged maximum ascending rate is 88 hPa and 83 hPa for PCMT and B85 runs respectively (see the zero lag). However, the three curves cross each other near the 4-hours lag. After that lag the order reverses and B85 shows the highest ascending rate. Therefore, even though B85 has less strong ascending rate maxima, it is the run for which trajectories exhibit more sustained ascents. To conclude, parameterized deep

275 convection tends to induce more sustained and longer-lasting ascending motion than when explicit deep convection occurs at grid scales of the model. The two schemes lead to the same qualitative effect but B85 is the one whose behavior distinguishes the most from explicit deep convection and presents more sustained ascents.
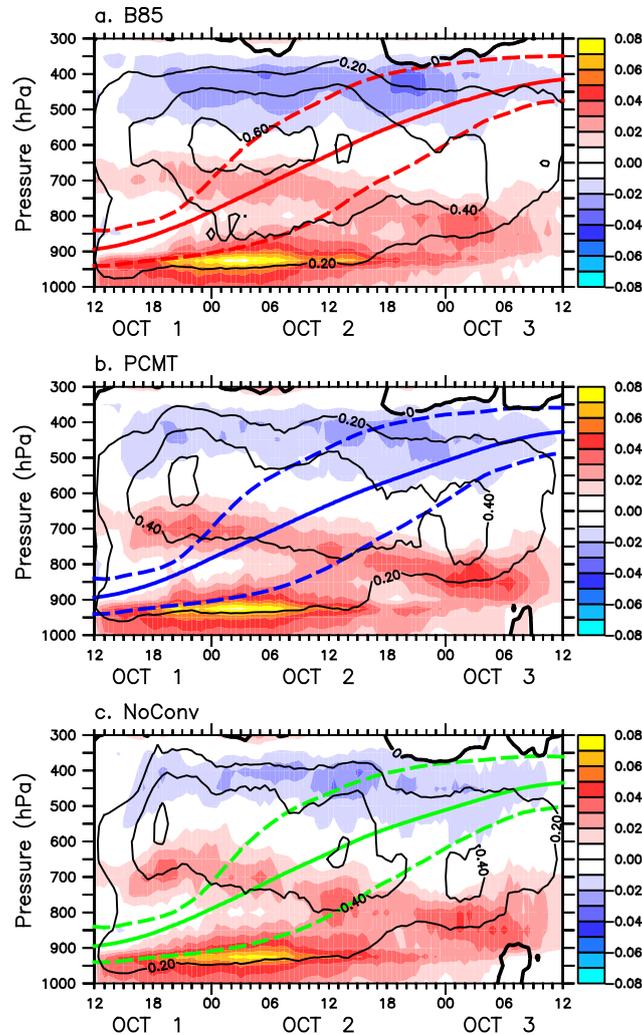

Figure 3. Time evolution of the mean vertical profiles along all WCB trajectories of the heating rate (int: 0.20 K h^{-1}) and PV tendency part due to the vertical derivative of the heating (int: 0.01 PVU h^{-1}) for (a) B85, (b) PCMT and (c) NoConv simulations. The mean pressure of the WCB trajectories is shown in solid lines and the 25th and 75th percentiles in dashed lines.

3.2 Differences in the rapid ascending trajectories during the first twelve hours of the simulations

To better visualize the effect of parameterized deep convection on heating rates in physical space, horizontal maps and vertical
280 cross sections are shown at 21 UTC 1 October in Fig. 5. This time has been chosen because it corresponds to large differences in the number of the most rapidly ascending trajectories (i.e those exceeding 100 hPa ascent within 2 hours) between the three runs (Fig. 2d). Only the positions of WCB trajectories belonging to this category are shown in Fig. 5. The cold and bent-back warm fronts bring strong similarities between the three runs. Additionally, heating rates are strong for all runs ahead of the cold
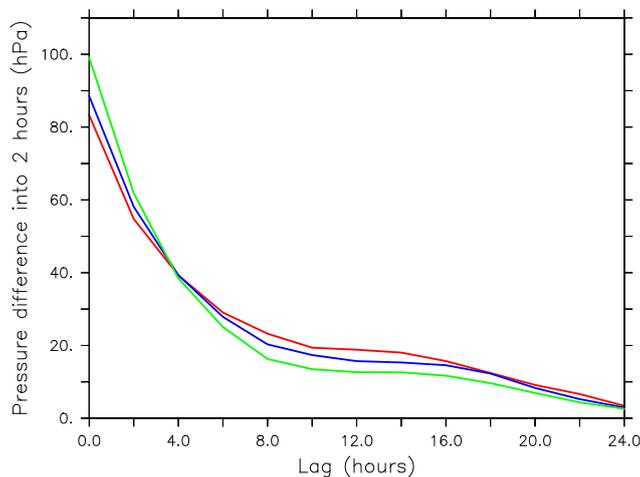

Figure 4. Time lag composite of the pressure difference in 2 hours over all WCB trajectories for B85 (red), PCMT (blue) and NoConv (green) simulations. The zero lag corresponds to the time of maximum pressure difference.

front within the WCB (right side of Figs. 5a,c,e) and in the vicinity of the bent-back warm front (upper left side of Figs. 5a,c,e).

285 Not surprisingly all the positions of the most rapidly ascending trajectories at that time are located within these regions of strong heating rate. However, large differences between the three runs appear in the heating rates along the WCBs and not near the bent-back warm front. Along the WCB, NoConv is characterized by 4 regions of strong heating rates with a few degrees extent in latitude and longitude and whose peak values are beyond 3 K h^{-1}. In the same area, PCMT shows similar peak values but the heating rates are more homogeneously distributed along the WCB than NoConv. In contrast, the peak values for B85

290 are much weaker (no more than 2.4 K h^{-1}) and the large values of heating rate are even more homogeneously distributed than in PCMT.

Vertical cross sections of the heating rates averaged between 42°N and 48°N, that is in the upstream side of the WCB, are shown in Figs. 5b,d,f. In that region, the heating rate is much stronger in NoConv and PCMT than in B85 over the whole tropospheric column. In NoConv, strong heating rates appear in the upper troposphere at pressure levels lower than 350 hPa

295 that do not exist for the two runs with parameterized convection. This yields to slightly lower isentropic levels in the upper troposphere for NoConv compared to the other two runs. However, it is worth mentioning there also exist regions where NoConv tends to get much smaller heating values along the WCB than the other two runs (see for instance the area centred at 28°W, 50°N). These results show similar findings as those of Martinez-Alvarado and Plant (2014) who compared two runs with full and reduced parameterized convection.

300 **3.3 Differences in the moderate ascending trajectories after 24-hours simulations**

Following Fig. 2d another particular interesting period is between 12 UTC and 18 UTC 2 October during which the number of trajectories with moderate ascents (25 hPa in 2 hours) becomes significantly larger for B85 than the other two runs. Heating

rates and trajectories having moderate ascents at 12 UTC 2 October are shown in Fig. 6. Compared to 15 hours earlier (Fig. 5),
the peak values of the vertically-averaged heating rates are weaker and significant differences between the runs appear along

305 the bent-back warm front. However, the qualitative picture is roughly the same. NoConv heating rate is more bumpy along
the front and marked by more pronounced regions of high and low heating rates than the other two runs. B85 is the run with
smoother heating rate (Figs. 6a,c,e). There are two particular regions of inactivity in NoConv; one located along the front at
26°W, 62N and another one further north between 63°N and 65°N and from 32°W to 24°W. PCMT exhibits slightly stronger
heating rates and more trajectories with moderate ascents than NoConv in those regions. But B85 gets even much stronger

310 heating rate and many more trajectories. The difference in the number of trajectories seen in Fig. 2d mainly comes from these
two regions.

Vertical cross sections of heating rates averaged between 63°N and 65°N show that the second region of marked WCB
inactivity in NoConv occurs at upper levels between 350 and 550 hPa in the longitudinal sector 34°W- 24°W. We do see many
more WCB trajectories with moderate ascents in B85 than in NoConv in association with the heating rate peak values of the

315 former being more than twice that of the latter (Figs. 6b,f). As already seen in many figures, PCMT has an intermediate behavior
between B85 and NoConv (Fig. 6d). A decomposition of the heating rate into various physical processes shows that differences
in the heating rates in that sector come from the large-scale heating and not the parameterized heating which is mainly negligible
at upper levels at that time (see Figures S1 and S2). Parameterized convection and turbulence have similar amplitudes as the
large-scale heating in the lower troposphere but are negligible compared to the large-scale heating at upper levels. The radiative

320 term is found to be much smaller than the other terms in that sector at that time over the whole troposphere. Therefore it is not a
direct effect of parameterized heating that is observed here but rather an indirect effect in which parameterized deep convection
interacts with the resolved flow so that it leads to a more active WCB region north of the front in the upper troposphere in B85
than in the other two runs.

Figure 7 provides a connection between the WCB activity, heating rates and PV patterns north of the front where large

325 differences between the three runs have been identified. At lower pressure than 450 hPa, two main regions of WCB activity
appears; one near 42°W-40°W in the vicinity of a well-marked localized negative PV region seen in all three runs (Figs. 7a,c,e)
and another one along the band 34°W-24°W discussed previously. Areas of negative PV are visible slightly above and west
of the latter region of WCB activity. These areas are small and centred at 32°W for PCMT and NoConv whereas it is much
larger and extends from 36°W to 32 °W in B85. More WCB trajectories in B85 than in the other two runs would be a good

330 explanation for the more extended negative PV area in B85. However, we observe that this negative PV area is not exactly
co-located with the positions of the WCB trajectories which are a bit below and more to the east relative to the negative PV
area (Fig. 7a). In other words, the PV loss undergone by WCB trajectories is not co-located with the negative PV area. To
explain this shift of the negative PV area relative to the PV destruction region, it is important to consider spatial redistribution
of PV by advection terms and in particular the indirect diabatic effects of advection by the non divergent wind which tends

335 to displace the PV destruction outward of the WCB outflow region (Archambault et al., 2013; Steinfeld and Pfahl, 2019).
Figures 7b,d,f show that the ageostrophic winds are stronger above 500 hPa between 36°W and 26°W in B85 than in PCMT
or NoConv as expected from its more intense WCB activity there. Between the WCB positions and the negative PV area

ageostrophic winds are upward and westward. Besides as they go further away from the WCB outflow region winds become more zonal and align more with the isentropic slopes as seen by comparing the orientation of the vectors with the slope of the

340 315 K isentropic surface near 36°W, 300 hPa in Fig. 7a. While the advection term is similar between the three runs between 44°W and 40°W, they significantly differ between 38°W and 36°W where negative PV advection is clearly stronger for B85. Therefore, stronger WCB activity in connection with higher heating rate in mid and upper troposphere leads to stronger PV loss in the WCB outflow region in B85 compared to the other two runs, which is then advected upward and westward by the stronger non divergent winds to form a more important zone of negative PV for the former run.

345 The findings of this section can be summarized as follows. With parameterized deep convection, heating rates are more homogeneously distributed along the cold and warm fronts while without parameterized deep convection, heating rates are marked by strong spatial variations along the fronts. This leads to more rapid instantaneous ascents for the latter and more moderate but more sustained ascents for the former. Martinez-Alvarado and Plant (2014) also emphasized the smooth and regulating effect of parameterized deep convection within WCB which is due to the fact that parameterized convection releases

350 convective instability at subgrid scales while explicit convection at resolved scales. Among the two schemes, B85 is the one having the greatest difference with NoConv while PCMT has a more intermediate behavior. The three runs significantly differ in terms of the impact of WCB activity on PV. B85 scheme generally leads to higher heating rates at upper levels and more PV destruction in the upper troposphere during the second half of the simulations.

4 Impact of deep convection representation on jet stream

355 The impact on the jet stream is investigated in the present section and forecast skills of the three runs are assessed by comparing to the re-analyses and airborne observations.

4.1 Comparison to (re)-analyses

PV horizontal maps at 300 hPa are shown for the three runs in Fig. 8 and compared with ECMWF-IFS and ARPEGE analyses and ERA5 reanalysis. The separation between stratospheric and tropospheric air is well marked in all panels by an abrupt jump

360 in PV from near-zero and negative values to large positive values close to 8-10 PVU. This limit is associated with a tropopause fold as shown in Figs. 7a,c,e. Despite this well-defined limit located more or less at the same place for the six datasets (3 simulations, 2 analyses and 1 reanalysis), the region of ridge building is not characterized by homogeneously distributed weak and negative PV values. For instance, at 64°N, going from 45°W to 25°W (i.e roughly along the main legs of the two Falcon flights), B85 exhibits large positive PV associated with stratospheric air, a sudden decrease to slightly negative values, then

365 another area of positive PV values and finally negative values (Figs. 7a and 8d). The area of positive PV within the ridge forms a band of PV with values varying between 0.5 and 1.5 PV largely covering the Greenland eastern coast (Fig. 8d) but whose vertical extent is rather limited between 300 and 350 hPa at 40°W (Fig. 7a). A similar narrow band of positive PV exists in the other datasets but with different values of PV and different locations. In ECMWF-IFS analysis and ERA5, the positive PV values are smaller but have the same location as in B85 (Figs.8a,c). In ARPEGE analysis, the band is rather similar in

370 intensity and location to B85 but this is not surprising since ARPEGE analysis is made using a deterministic forecast whose
deep convection scheme is B85. In contrast, in NoConv the band is eastward shifted by few degrees in longitude compared
to B85 (Figs. 7e and 8f). In PCMT, the band is less well defined and the pattern resembles a mix between those of B85 and
NoConv patterns.

Because there are two jumps in PV at 300 hPa, a double jet structure is well visible in Fig. 9 for all datasets with the main
375 jet being the one more to the northwest separating the tropospheric air from the stratospheric air. While the secondary jet lies
just above the Greenland eastern coastline for ECMWF-IFS, ARPEGE analyses, ERA5 and B85 (Figs. 9a-d), it is located
further east in PCMT and NoConv (Figs. 9e-f). Anomalies with respect to ECMWF-IFS analysis are shown in black contours
in Figs. 9d-f. While B85 run produces a slightly too strong jet with positive anomalies of 4 m s^{-1} amplitude (Fig. 9d), the
other two runs are marked by an eastward shift of the jet and negative anomalies of the order of 8 m s^{-1} amplitude over the
380 Greenland eastern coastline (Figs. 9e-f). At that time, B85 performs better than PCMT or NoConv in capturing the double jet
stream structure and this is attributed to the more active WCB in that region in B85 that reinforces the PV gradient further west
and pushes the secondary jet closer to the main one. Another interesting feature is the stronger wind magnitude of the main jet
in PCMT and NoConv compared to B85. This is due to more negative PV values just east of the tropopause fold (Figs. 8d-f)
and more active WCB in that area for the former runs than the latter (see 42°W in Figs. 7a,c,e). Here also, B85 is slightly
385 closer to ECMWF-IFS than the other two runs. In other words, the WCB outflow region is separated into two branches one
reinforcing the main jet and the other one the secondary jet. The runs distinguish from each other in the relative importance of
the two branches.

Six hours later, at 18 UTC 2 October, the double jet structure is much less pronounced in ECMWF-IFS, ARPEGE analyses
and ERA5 as well as in PCMT and NoConv but is still there in B85 (Fig. 10). Furthermore, the anomalies with respect to
390 ECMWF-IFS are larger north of 64°N in B85 than PCMT or NoConv. In that case, B85 does not perform better than the other
two runs and is even less skillful. Further south, the jet stream is too weak in NoConv compared to the other datasets (see lower
right side of the panels in Figs.10d-f) but this sector is not the focus of the present study as no flights were conducted there.

4.2 Comparison to aiborne observations

The flights of the two aircrafts occurring in the region of the double jet structure (Fig. 9), it is worth comparing the three
395 forecasts to airborne observations to determine which one performs better in representing the jet stream structure and intensity.
The two aircrafts followed each other with 10-minutes lag and observed the same meteorological features during more than half
of the flights duration. Besides, since the Doppler radar on board the SAFIRE Falcon and the Doppler lidar on board the DLR
falcon are not sensitive to the same particles of the atmosphere, they provide complementary datasets as seen in Figs. 11a,b.
The data has been interpolated at the model grid in the present study (Sect. 2.3.2) while higher-resolution profiles of the same
400 datasets are shown in Fig. 9 of Schäfler et al. (2018).

In Fig. 11a, a good correspondence generally appears between the three kinds of measurements, Doppler radar, airborne
in-situ and the nine dropsondes. The intensities of the lower- and upper-level jets detected close to the Greenland coastline are
similar in the dropsondes and radar data. The three datasets also agree on the intensities of the upper-level wind magnitude;

two main regions of high values are distinguishable, one between 9.5 h and 9.7 h and the other between 9.8 h and 10 h. Some local discrepancies also occur for instance between the dropsonde data and radar data at 10.1 h or between the dropsonde data and in-situ aircraft measurements at 10.5 h. The presence of a double jet structure is confirmed by the lidar measurements of the DLR Falcon (Fig. 11b) with the two jets being quite close to each other.

Figs. 11c-e show the wind magnitude of the three forecasts. The double jet structure is present in all three runs as already shown in Fig. 9 but once again we do see that the distance between the two jets is significantly larger for PCMT and NoConv than B85. B85 is the forecast with the closest patterns to the observations even though the distance between the two jets is still slightly too large in that run (e.g., compare Figs. 11b and c).

To better visualize differences between forecasts and observations, forecast errors with respect to the observations made during the SAFIRE Falcon flight are shown in Fig. 12. While the three forecasts share the same errors at low levels with a too strong low-level jet in the vicinity of Greenland (see near 9.8 h and 10.6 h), errors in the upper troposphere have not the same magnitude among the three forecasts. Between 200 and 400 hPa, PCMT and NoConv forecast errors exhibit tripolar anomalies (positive-negative-positive) between 9.2 h and 9.9 h and between 10.7 h and 11.1 h whose magnitude is about 12 m s^{-1}. The negative forecast errors shown at 9.4 h and 10.9 h are consistent with the negative anomalies shown in Figs. 9e,f in which the reference is ECMWF-IFS analysis. In contrast, B85 errors fluctuate between 6 and 9 m s^{-1} only. To conclude, comparison with airborne observations confirms that B85 performs better than the other two forecasts in the location of the jets at 24-hour lead time.

5   Conclusions

The effect of parameterized deep convection on WCB activity and jet stream has been investigated by performing simulations of an explosively-developing large-scale cyclone that occurred during NAWDEX using the Météo-France global atmospheric model ARPEGE. Three simulations differing only from their deep convection representation are analysed. For two of them, parameterized deep convection was activated with distinct schemes (B85 corresponding to Bougeault (1985) scheme and PCMT corresponding to Piriou et al. (2007) scheme) while for the third one, parameterized convection was turned off. The main findings can be summarized as follows and correspond to answers to the three main questions raised in the introduction:

– When parameterized deep convection is inactive, convective instability is released at the resolved scales such that few localized cells of few degrees extent in longitude and latitude appear along the cold and warm fronts of the cyclone. These localized cells are characterized by strong heating and fast ascending motion. In contrast, when parameterized deep convection is active, heating rate is more homogeneously distributed along the fronts, its large values are more spread out while having less strong maxima than when deep convection is explicit at the model grid scales. This results in different behaviors in WCB ascents: without parameterized deep convection, ascents are rapid and abrupt while with parameterized deep convection, ascents are more moderate but more sustained. These results confirm the regulating effect of parameterized deep convection emphasized by Martinez-Alvarado and Plant (2014).

- Explicit convection yields strong localized heating over the whole troposphere that may potentially have a more important impact on the upper-level circulation locally than parameterized deep convection. However, the heating rate averaged over all WCB trajectories was found not to be stronger for explicit deep convection than parameterized deep convection. Moreover, between 1-day and 2-day lead times, one of the scheme (B85) shows more important averaged heating in the upper troposphere and more important vertical gradients of heating that lead to more PV destruction. This stronger heating can be attributed to the large-scale heating and not the parameterized heating which is mainly localized at lower levels.These results should be contrasted with Done et al. (2006) who found that explicit convection yielded more PV destruction than parameterized convection in their case study. The present results also show that differences in WCB activity between explicit and parameterized deep convection may lead to large differences in the jet stream position and intensity at 1-day lead time. This is to be contrasted with Martinez-Alvarado and Plant (2014). who found rather modest impacts at the same short range. The impact on the upper-tropospheric circulation may depend on case studies. Here the extratropical cyclone is deeper that the one studied by Martinez-Alvarado and Plant (2014).

- The effects of the two deep convection schemes on WCB and their impact on the jet stream significantly differ from each other. B85 is the scheme inducing the most drastic differences compared to the run with explicit deep convection while PCMT has a more intermediate behavior. In terms of the impact on the jet stream, PCMT is closer to the run with explicit deep convection than to B85. Comparison with operational analyses and airborne observations of different types helped us to unambiguously determine the most skillful forecasts. At 1-day lead time, B85 performed better than the other two runs to represent the double jet structure. The shorter distance between the main and secondary jets in B85 than in other two forecasts was found to be more realistic in B85. This was attributed to a more active branch of the WCB in a region of the upper troposphere that pushed the secondary jet closer to the main one. However, at longer forecast range, this effect was too strong and led to less realistic behavior in B85 than the other two runs. Therefore, it suggests that the more active dynamics in the upper troposphere in B85 is consistent with observations and (re)-analysis. This behavior lacks in the other two runs but it is found to be too strong in B85.

An analysis of the jet stream representation by the other members of the ARPEGE EPS show that members 1, 2, 4, 5 and 9 behave similarly to member 0, which is the B85 run discussed in the present study (Figure S3). All these members share the same deep convection scheme, that is B85, while differing in the representation of other processes such as turbulence, shallow convection or oceanic flux. In contrast, members 3, 6, 7 and 8 resemble each other and are marked by a larger distance between the two jets than for the other set of members. The deep convection scheme of members 6, 7 and 8 is PCMT while that of member 3 is the B85 scheme in which the humidity convergence closure has been replaced by the CAPE closure. Since PCMT is also based on the CAPE closure, it indicates that the main difference in the jet representation between PCMT and B85 largely comes from the closure. Further investigations would be needed to better estimate the role of the convective closure type (such as CAPE closures versus moisture convergence closures) on the difference in cyclogenesis, WCB and jet stream dynamics. One way would be to analyze the mirror experiment, that is PCMT closed with moisture convergence. The other way would be to run the B85 scheme by arbitrarily multiplying the intensity of the humidity convergence by a given factor in the closure, to

470   investigate the sensitivity of WCB to convective intensity in the different regions of the WCB. These sensitivity experiments
would necessitate a full analysis and could be an interesting aspect to investigate in future studies.

The sensitivity to initial conditions have been analyzed to check the robustness of the results. Starting the simulations 12
hours earlier leads to similar findings: a too large distance between the two jets and a weaker secondary jet for PCMT compared
to B85 (not shown). For hindcasts starting at even earlier dates (e.g., 30 September), members share similar forecast errors in

475   the representation of the jet stream and it is more difficult to state which one performs better but we still observe a more intense
secondary jet in B85.

Similar numerical simulations of the subsequent cyclone that followed the Stalactite cyclone two days after have been also
analysed (IOP7; Schäfler et al., 2018). In that case, generation of negative PV at the tropopause level was found to be more
pronounced in B85 than PCMT leading to a stronger jet in the former than in the latter. The intermediate case based on B85

480   scheme but activated with CAPE closure resembles simulations based on PCMT scheme (not shown). These results corroborate
the case study of the Stalactite cyclone and support the idea that WCB in B85 is in average more active in the upper troposphere
in connection with the humidity convergence closure.

While the focus of the present study was on the impact of parameterized deep convection in the WCB outflow region, a
companion paper will follow up to provide a more detailed analysis on the effect of parameterized deep convection in the

485   ascending branch of the WCB and the depth of the jet stream (Wimmer et al., in preparation). It will rely on observations made
during the second flight of SAFIRE Falcon on 2 October.

Author contributions. GR and PA designed the initial study. GR and MW performed the data analysis, MW computed the Lagrangian

490   trajectories and GR made the figures. CL performed the ARPEGE simulations with the help of JMP. PA developed the Lagrangian trajectory
algorithm. JD, QC, and JP provided the observational datasets. All authors contributed to the scientific discussions.

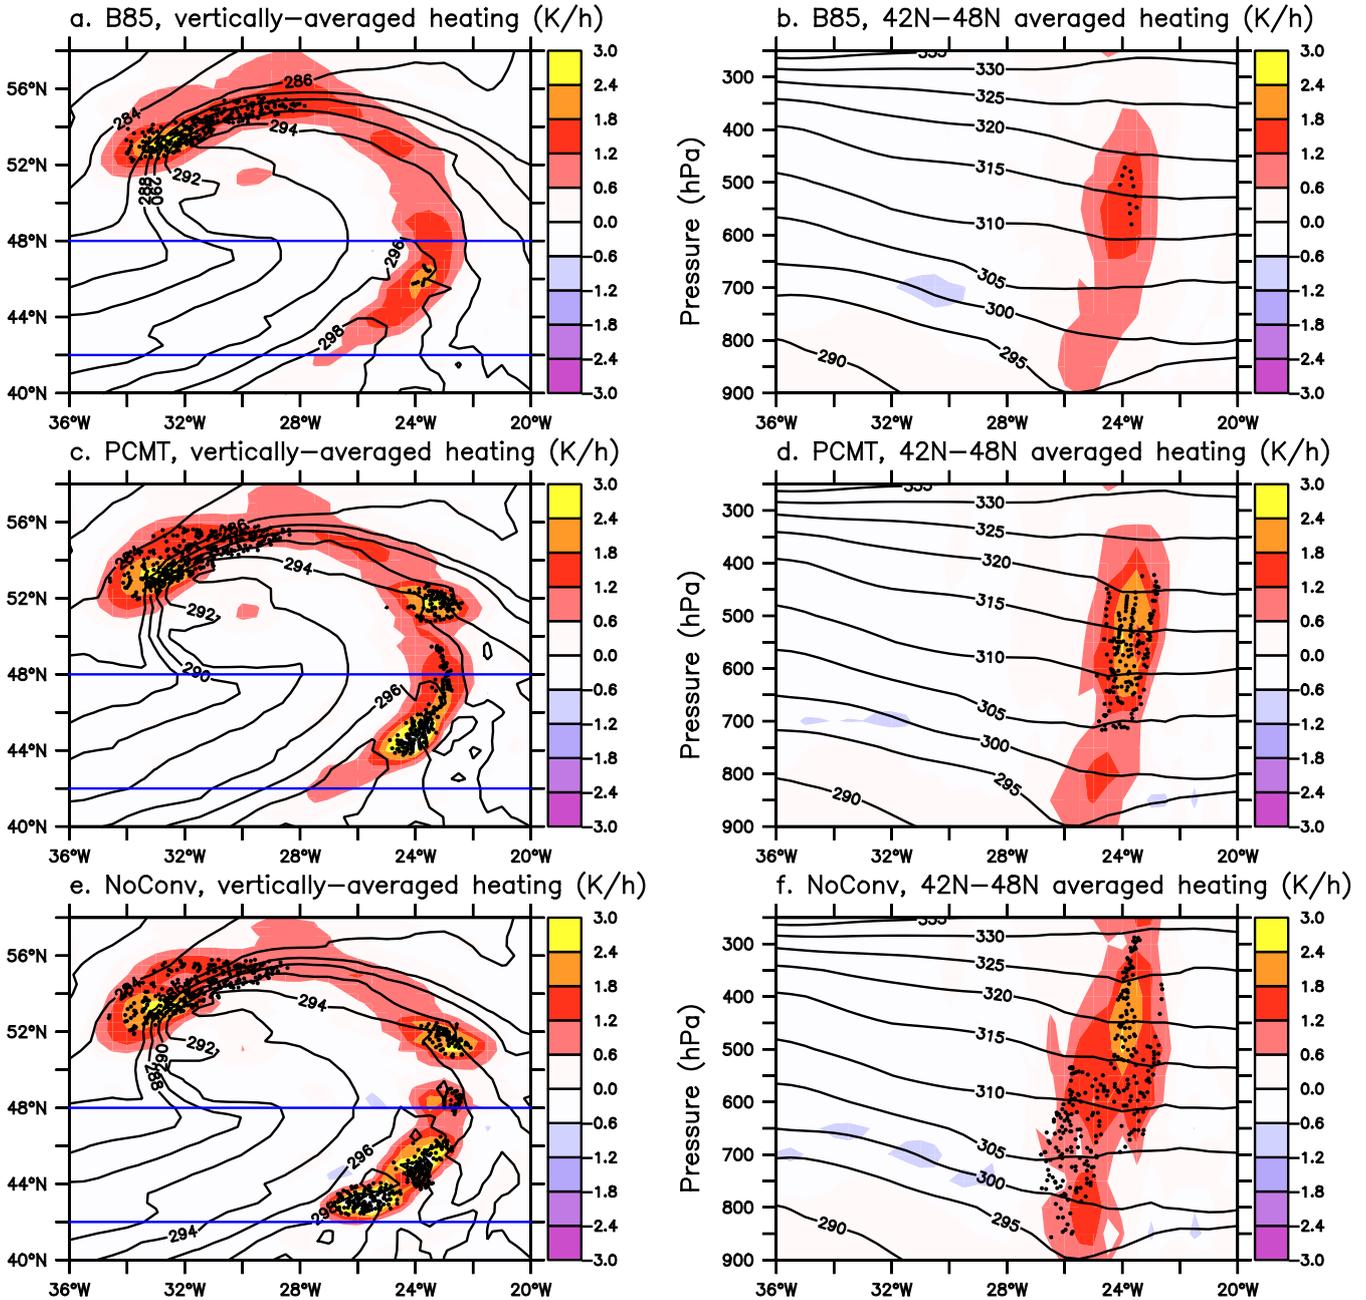

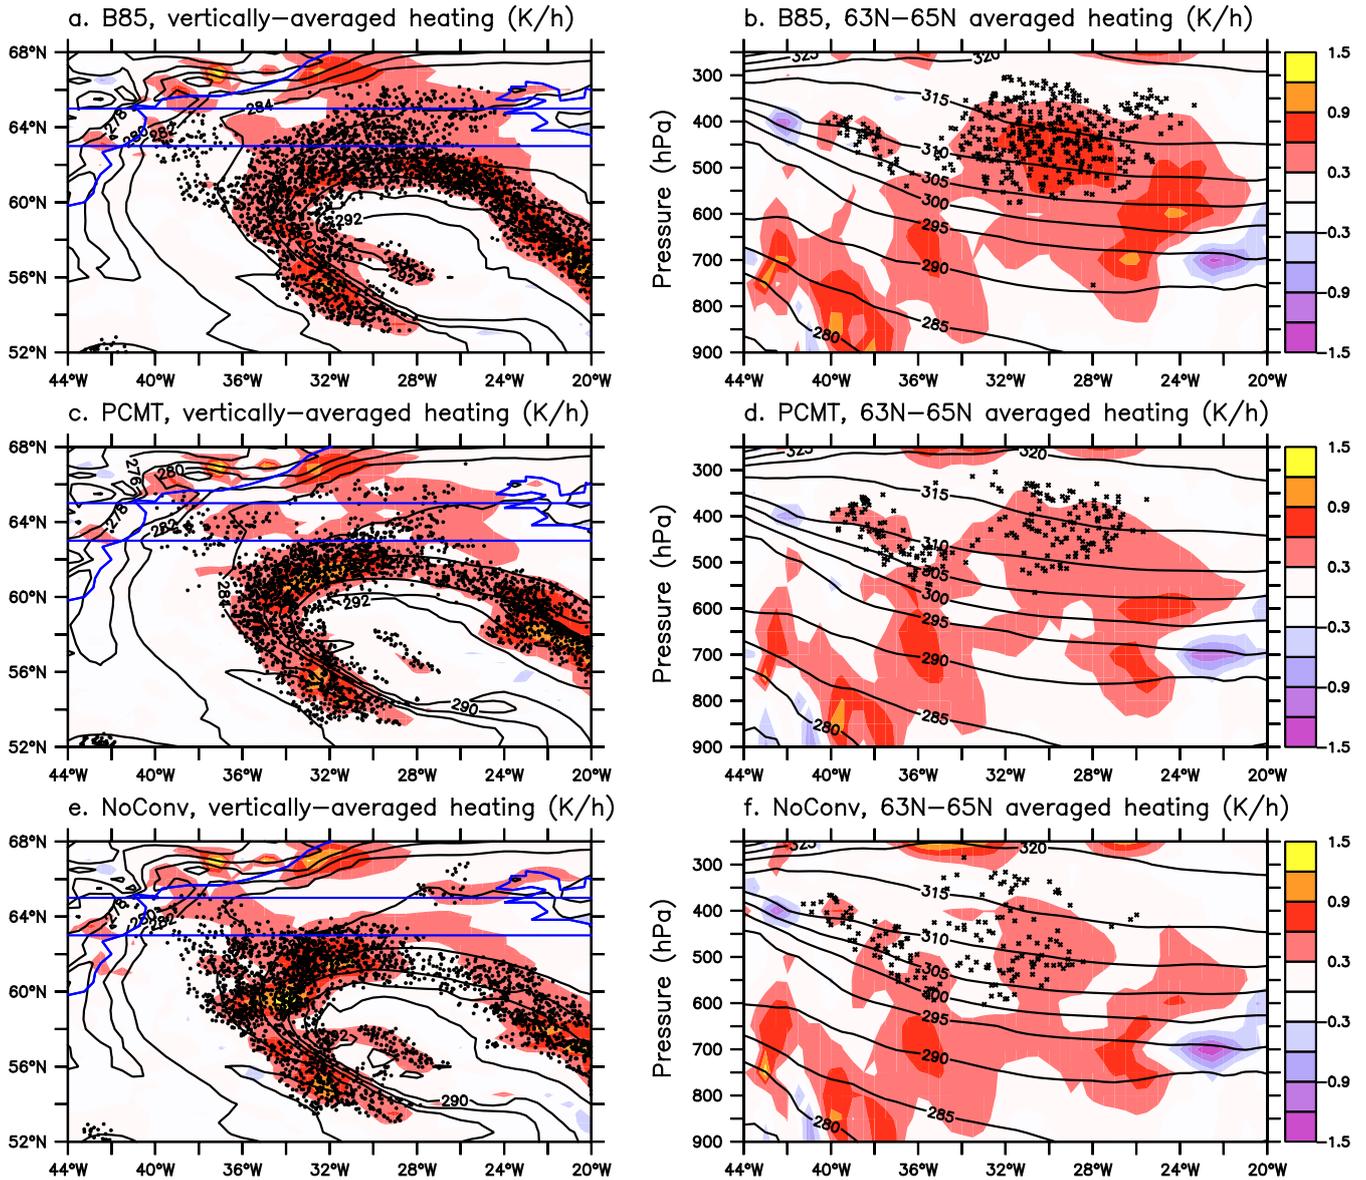

Figure 5. (Left panels) vertically-averaged heating rate between 300 and 800 hPa (shadings; units: K h^{-1}), potential temperature at 850 hPa (int: 2 K) and WCB trajectories satisfying 100 hPa ascent in 2 hours at 21 UTC 1 October for (a) B85, (c) PCMT and (e) NoConv simulations. (Right panels) latitudinally-averaged (42°N-48°N; see blue lines in panels a, c and e) heating rate (shadings; units: K h^{-1}), potential temperature (contours; int: 5 K) and WCB trajectories satisfying 100 hPa ascent within 2 hours and located in the same latitudinal band at 21 UTC 1 October for (b) B85, (d) PCMT and (f) NoConv simulations.

Figure 6. (Left panels) vertically-averaged heating rate between 300 and 800 hPa (shadings; units: K h^{-1}), potential temperature at 850 hPa (int: 2 K) and WCB trajectories satisfying 25 hPa ascent in 2 hours at 12 UTC 2 October for (a) B85, (c) PCMT and (e) NoConv simulations. (Right panels) Latitudinally-averaged (63°N-65°N; see blue lines in panels a, c and e) heating rate (shadings; units: K h^{-1}), potential temperature (contours; int: 5 K) and WCB trajectories satisfying 25 hPa ascent in 2 hours and located in the same latitudinal band at 12 UTC 2 October for (b) B85, (d) PCMT and (f) NoConv simulations.
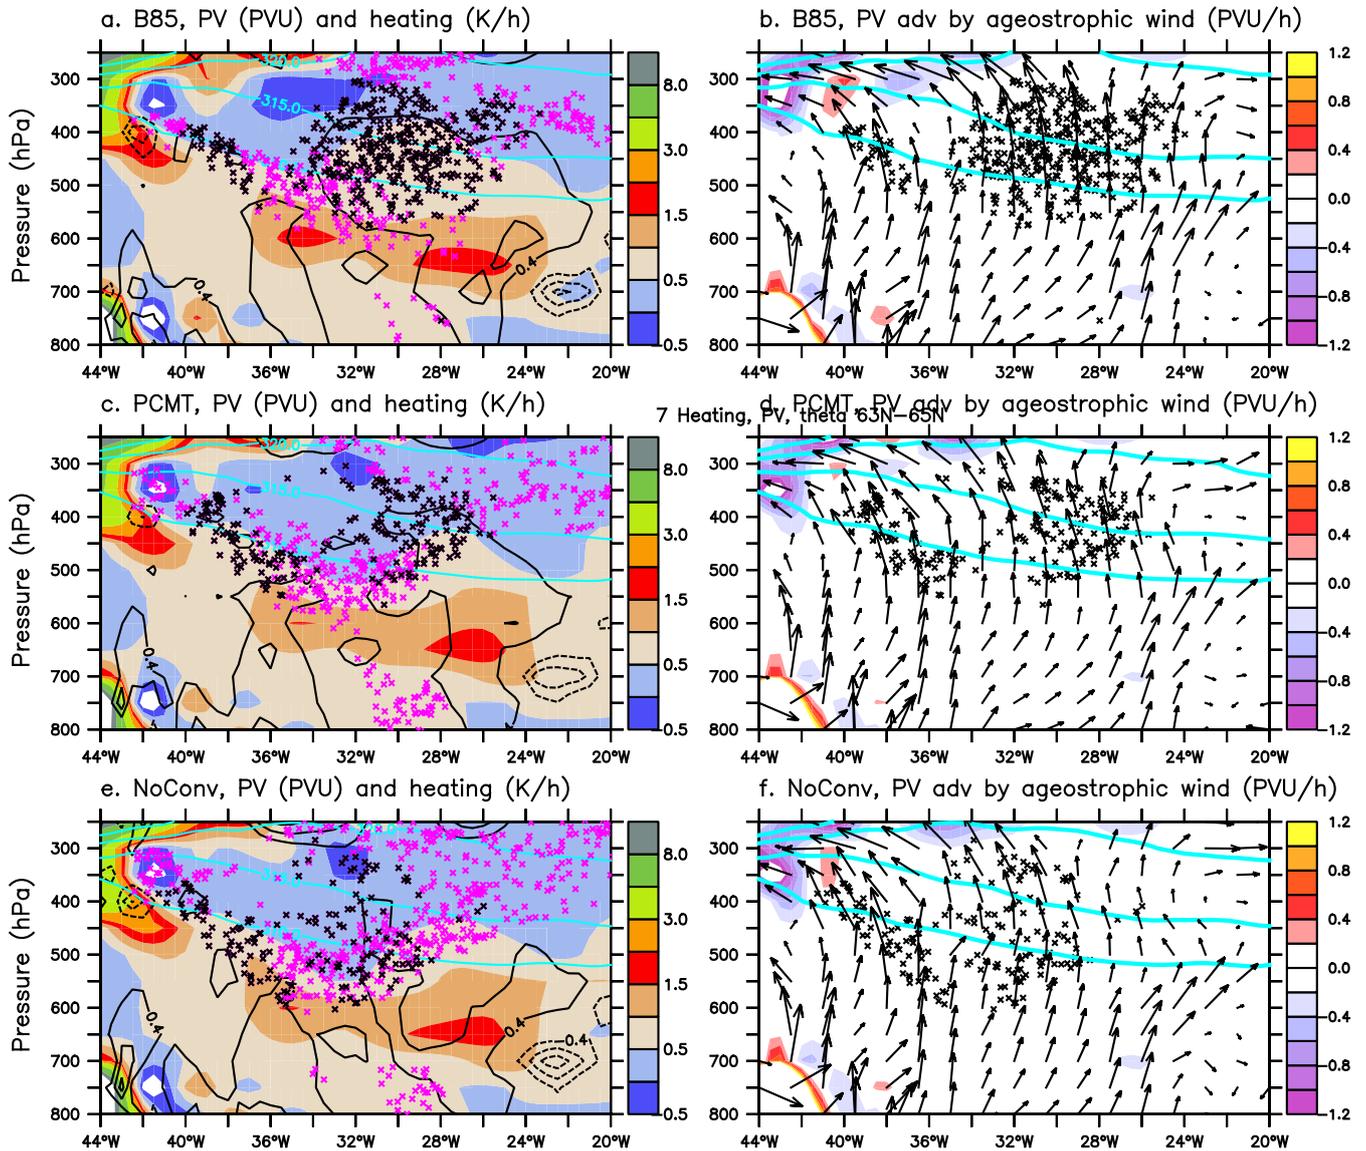

Figure 7. (Left panels) Latitudinally-averaged (63°N-65°N) PV (shadings; units: PVU), heating rate (black contours; int: 0.4 K h^{-1}), potential temperature (light blue contours for 310, 315, 320 and 325 K) and WCB trajectories satisfying 25 hPa ascent in 2 hours (black crosses) and the other WCB trajectories (purple crosses) and located in the same latitudinal band at 12 UTC 2 October for (a) B85, (c) PCMT and (e) NoConv simulations. (Right panels) Latitudinally-averaged (63°N-65°N) PV advection by the zonal and vertical components of the ageostrophic wind (shadings; units: PVU h^{-1}), and the associated ageostrophic wind vectors (black arrows). The light blue contours represent potential temperature as in left panels. The ageostrophic wind vectors are represented by multiplying respectively the zonal and vertical components by the distances occupied by 1 meter in longitude and 1 Pa in pressure on the diagram.
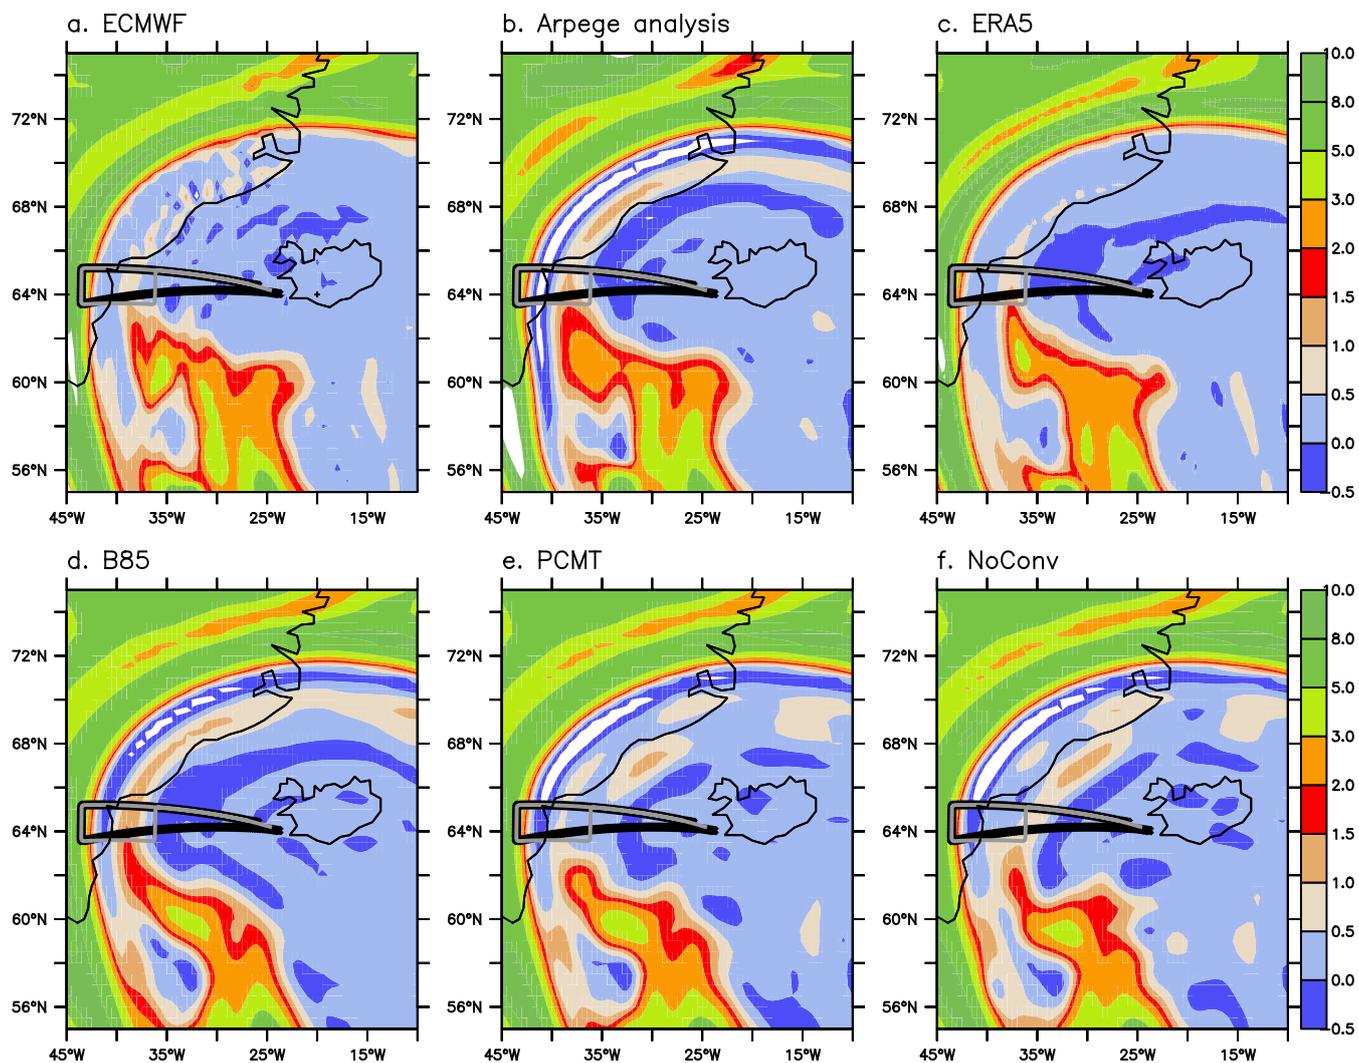

27

Figure 8. Potential vorticity (units: PVU) at 300 hPa at 12 UTC 2 October for (a) ECMWF-IFS operational analysis, (b) ARPEGE operational analysis, (c) ERA5 reanalysis, (d) B85 run, (e) PCMT run and (f) NoConv run. The black and grey lines correspond to the SAFIRE and DLR Falcon flights that occurred between 09 UTC and 12 UTC 2 October in an anticlockwise direction.
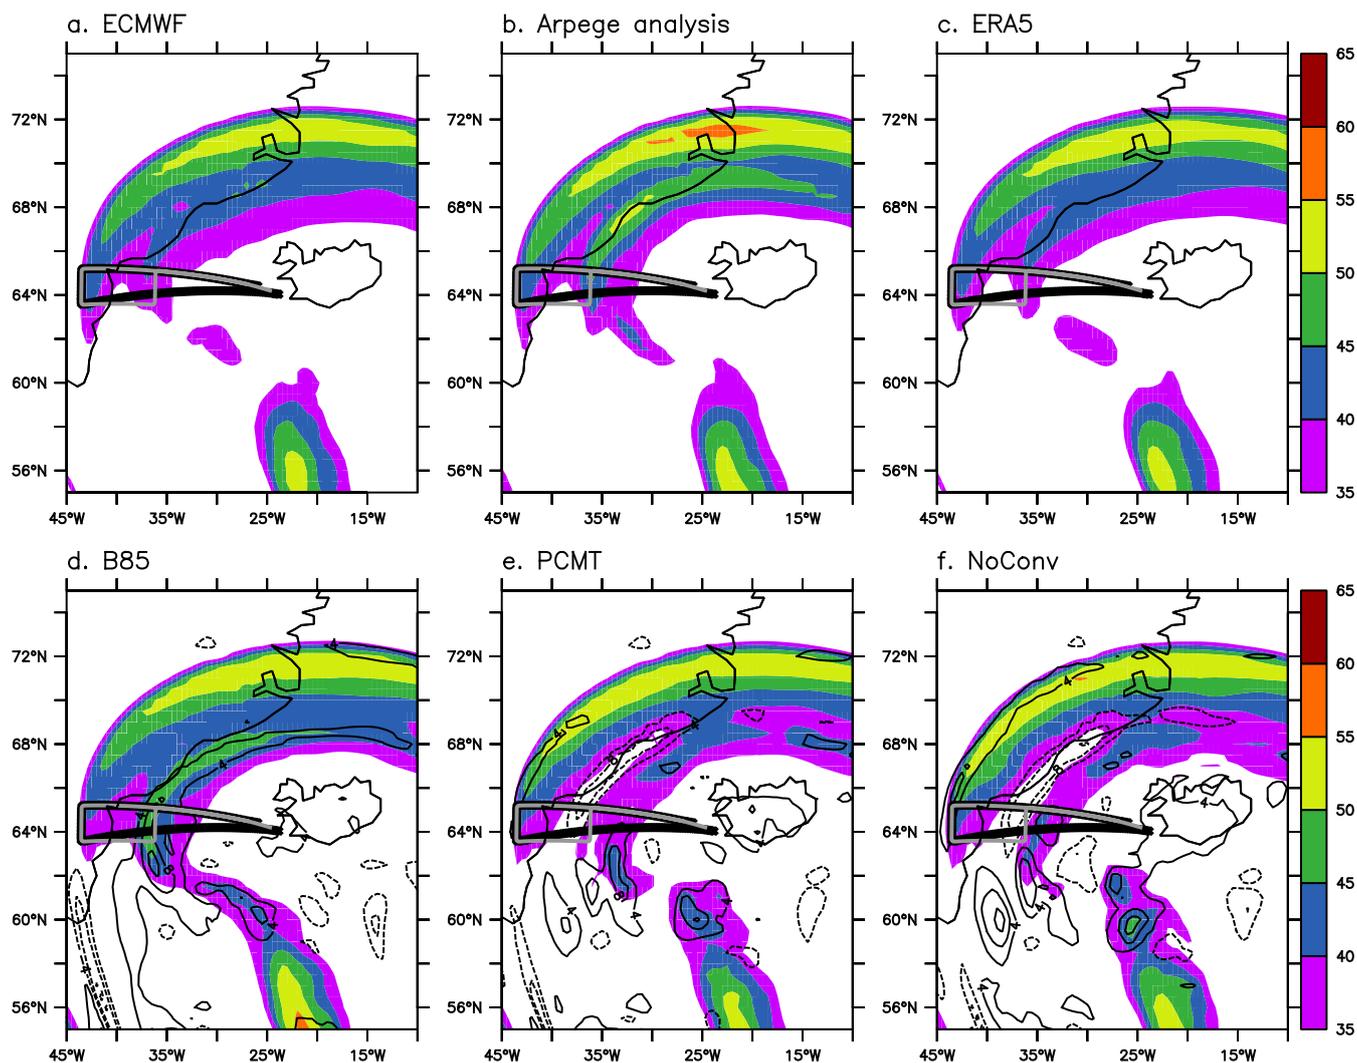

Figure 9. Wind speed (shadings; units: m s^{-1}) at 300 hPa at 12 UTC 2 October for (a) ECMWF-IFS operational analysis, (b) ARPEGE operational analysis, (c) ERA5 reanalysis, (d) B85 run, (e) PCMT run and (f) NoConv run. In (d)-(f), the black contours represent the wind speed anomalies (int: 4 m s^{-1}) of the three runs with respect to the ECMWF-IFS operational analysis. The black and grey lines correspond to the SAFIRE and DLR Falcon flights that occurred between 09 UTC and 12 UTC 2 October in an anticlockwise direction.
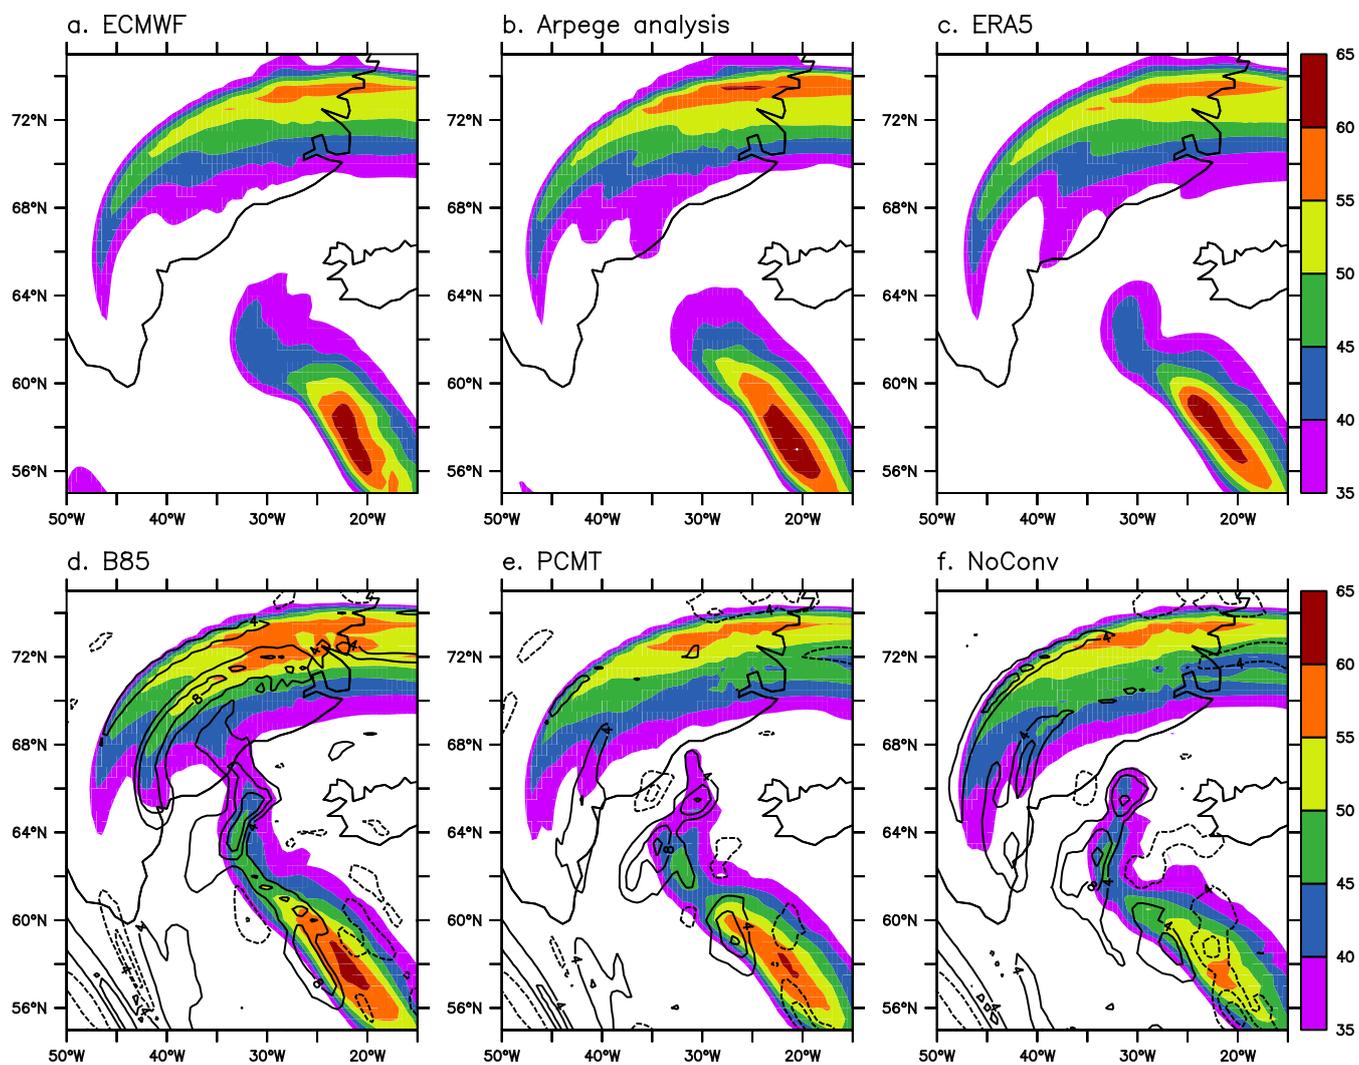

**Figure 10.** As in Figure 9 but at 18 UTC 2 October.

Figure 11. Wind speed (units : m s^{-1}) as function of time: (a) derived from the SAFIRE Falcon Doppler radar RASTA, airborne in-situ measurements (upper coloured line) and dropsondes (coloured circles) along the whole flight track, (b) derived from the DLR Falcon 2-μm Doppler wind lidar along part of the flight common to the SAFIRE flight, and from (c) B85, (d) PCMT and (e) NoConv runs along the SAFIRE flight track. In (a), (b) the measured wind speeds have been interpolated on the model grid. In (c)-(e), the wind speed data is derived from 15-minute output centered on the time of interest. See section 2.3.2 for further details on the interpolations procedure.
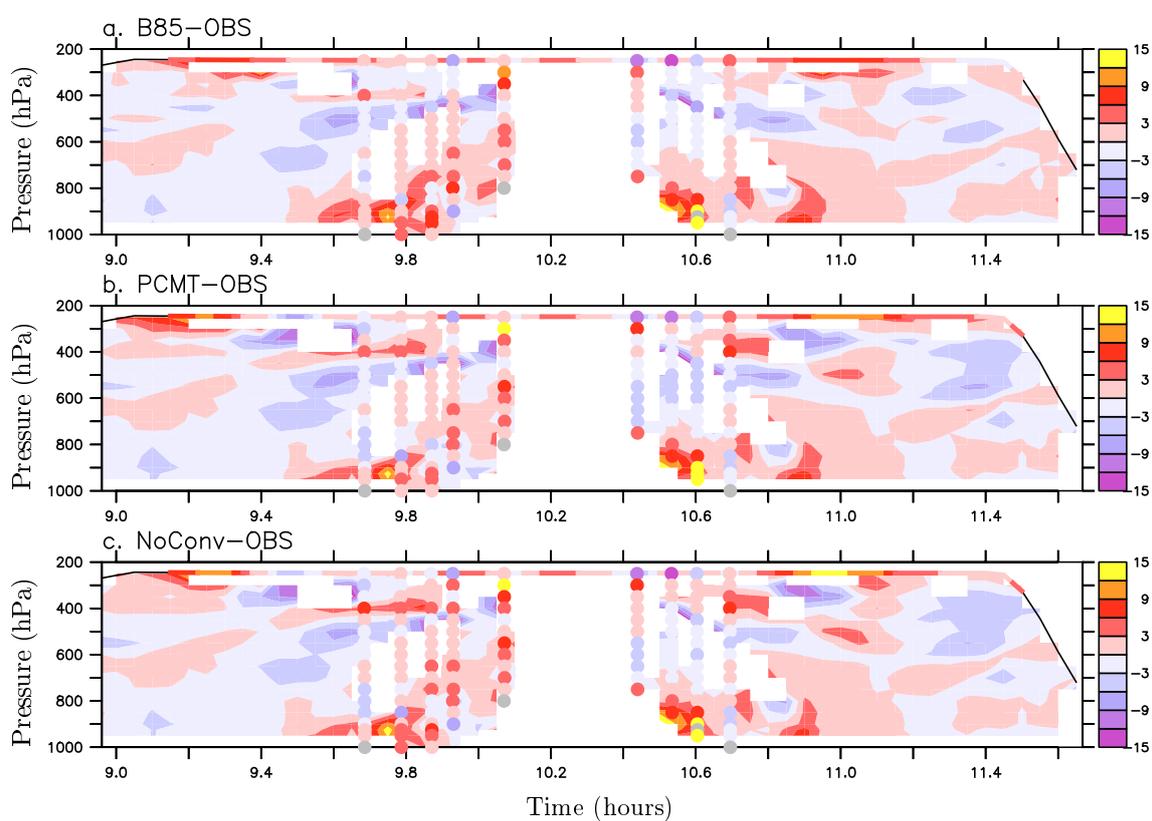

Figure 12. Difference (experiment - observations) in wind speed (units: m s^{-1}) for (a) B85, (b) PCMT and (c) NoConv simulations. The wind observations are composed of dropsondes, airborne in-situ measurements and Doppler radar measurements along the SAFIRE Falcon track.
