**Correspondence:** Leonie Villiger (leonie.villiger@env.ethz.ch)

**Abstract.** Shallow clouds in the trade-wind region over the North Atlantic contribute substantially to the global radiative budget. In the vicinity of the Caribbean island Barbados, they appear in different mesoscale organisation patterns with distinct net cloud radiative effects (CRE). Cloud formation processes in this region are typically controlled by the prevailing large-scale subsidence. However, occasionally weather systems from remote origin cause significant disturbances. This study investigates the complex cloud-circulation interactions during the field campaign EUREC<sup>4</sup>A (Elucidate the Couplings Between Clouds, Convection and Circulation) from 16 January to 20 February 2020, using a combination of Eulerian and Lagrangian diagnostics. Based on observations and ERA5 reanalyses, we identify the relevant processes and characterise the formation pathways of two moist anomalies above the Barbados Cloud Observatory (BCO), one in the lower ( $\sim 1000$ -650 hPa) and one in the middle troposphere ( $\sim 650$ -300 hPa). These moist anomalies are associated with strongly negative CRE values and with contrasting long-range transport processes from the extratropics and the tropics, respectively. The low-level moist anomaly is characterised by an unusually thick cloud layer, high precipitation totals and a strongly negative CRE. Its formation is connected to an “extratropical dry intrusion” (EDI) that interacts with a trailing cold front. A quasi-climatological (2010-2020) analysis reveals that EDIs lead to different conditions at the BCO depending on how they interact with the associated cold front. Based on this climatology, we discuss the relevance of the strong large-scale forcing by EDIs for the low-cloud patterns near the BCO and the related CRE. The second case study about the mid-tropospheric moist anomaly is associated with an extended and persistent mixed-phase shelf cloud and the lowest daily CRE value observed during the campaign. Its formation is linked to “tropical mid-level detrainment” (TMD), which refers to detrainment from tropical deep convection near the melting layer. The quasi-climatological analysis shows that TMDs consistently lead to mid-tropospheric moist anomalies over the BCO and that the detrainment height controls the magnitude of the anomaly. However, no systematic relationship was found between the amplitude of this mid-tropospheric moist anomaly and the CRE at the BCO. Overall, this study reveals the important impact of the long-range transport, driven by dynamical processes either in the extratropics or the tropics, on the variability of the vertical structure of moisture and clouds, and on the resulting CRE in the North Atlantic winter trades.

## 1 Introduction

The representation of trade-wind cumuli in model simulations critically influences climate projections (e.g., Bony et al., 2015; Schneider et al., 2017; Zelinka et al., 2017). These clouds form from the complex interplay of turbulent mixing, shallow convection, cloud radiative processes and large-scale subsidence within the descending branch of the Hadley circulation (Webb et al., 2015; Vial et al., 2016, 2017). In return, they modulate the thermodynamic conditions in their environment (Bony et al., 2017) and can induce mesoscale circulations (Naumann et al., 2017) through diabatic processes. Thus, clouds and the atmospheric circulation are closely tied to each other on various scales.

This study investigates the influence of meridional long-range transport on the formation of moist anomalies and trade-wind clouds during the field campaign EUREC<sup>4</sup>A (Elucidate the Couplings Between Clouds, Convection and Circulation; Bony et al., 2017; Stevens et al., 2021), which took place in early 2020 in the vicinity of the Caribbean island Barbados. A particular focus is set on periods when the thermodynamical vertical profile deviates from what is typically expected in the trade-wind region, i.e., a shallow cloud layer with a dry free troposphere aloft. The study has three research aims: (1) to characterize the variability in the large-scale circulation during EUREC<sup>4</sup>A and its influence on the variability in the thermodynamical vertical profile over Barbados; (2) to analyse the transport and processes during this transport that lead to the formation of moist anomalies and clouds in the lower and middle troposphere, respectively; and (3) to quantify the climatological frequency of the identified transport pathways and of the robustness of their link with moist anomalies. In the following paragraphs, we provide further information about the field campaign as well as the processes related to dry intrusions and detrainment from deep convective clouds near the melting layer, which are both essential features for the moist anomalies analysed in this study.

Providing simultaneous observations from multiple platforms complemented with a substantial modelling effort, EUREC<sup>4</sup>A aims at deepening our understanding of the cloud-circulation coupling in the trades (Bony et al., 2017; Stevens et al., 2021). Already before the field campaign, the clouds near Barbados were a matter of active research. It is known that they organise in four different mesoscale patterns (Stevens et al., 2020) with distinct radiative effects (Bony et al., 2020) and in response to differing environmental conditions (Schulz et al., 2021). Furthermore, the cloudiness in this region is known to undergo a daily cycle, which peaks in the early morning (Vial et al., 2019). Barbados represents an ideal site for studying shallow trade-wind cumuli (Medeiros and Nuijens, 2016; Stevens et al., 2016) and has been the base for many previous field experiments, e.g., BOMEX (1969; Holland, 1970), RICO (2004/2005; Rauber et al., 2007), CARRIBA (2010/2011; Siebert et al., 2013), Narval I (2013; Stevens et al., 2016) and II (2016; Stevens et al., 2019).

Due to its location at the edge of the tropics, the region of Barbados experiences large-scale subsidence at upper levels and prevailing low-level easterlies during boreal winter. The subsidence rate at upper levels results from the balance between radiative cooling and adiabatic warming and is estimated to be  $35 \text{ hPa} (24 \text{ h})^{-1}$  (Salathé and Hartmann, 1997). However, this typical trade-wind regime is frequently disturbed by intrusions from either sides, i.e., the extratropics or deep tropics. The Lagrangian perspective is useful to investigate such disturbances as it allows us to identify the origin and transport history of individual air parcels eventually arriving in the trade-wind region. This approach has been adopted previously in several studies, e.g., to investigate the origin of dry and humid layers in the (sub)tropics (Yoneyama and Parsons, 1999; Waugh, 2005; Cau

et al., 2005, 2007) or to link the cloudiness in Barbados to the large-scale transport (e.g., Aemisegger et al., 2021; Schulz et al., 2021). Here, we use it to study the formation of moist anomalies above Barbados and, more specifically, to identify air parcels that (1) rapidly descend from the upper-level extratropics towards Barbados, so-called dry intrusions (DI, e.g., Browning and Roberts, 1994; Browning and Golding, 1995; Wernli, 1997, we use here the abbreviation EDI to emphasize the extratropical origin); or (2) flow out of deep and mid-level convective systems over tropical South America and spread over Barbados at mid (e.g., Johnson et al., 1996, 1999; Stevens et al., 2017) or upper levels. Depending on the detrainment height, we refer to this phenomenon as tropical mid-level (TMD) or upper-level (TUD) detrainment.

EDIs are coherent dry airstreams that descend from near-tropopause levels into the middle or lower troposphere in the rear of extratropical cyclones (e.g., Browning, 1997; Raveh-Rubin, 2017). They are visible in water vapour satellite images as dry slots with a moisture front at their leading edge (Browning and Golding, 1995; Browning, 1997). The dry layer induced by the EDI potentially increases outgoing longwave radiation up to  $3 \text{ W m}^{-2}$  per 100 m of the layer's depth (Cau et al., 2005). As shown by Browning and Golding (1995), EDI air parcels have a distinct impact on surface precipitation depending on whether they under- or overrun the so-called warm conveyor belt (WCB), i.e., a moist ascending airstream ahead of the cold front. In the first case, the EDI might suppress precipitation by evaporating the falling hydrometeors. In the second case, potential instability builds up that results in convective precipitation if it is released. At times, EDIs are related to upper-level Rossby-wave breaking, which forms narrow tongues of stratospheric air with high potential vorticity (PV). If such a tongue of high PV air, also referred to as a PV streamer (Appenzeller and Davies, 1992) extends into the tropics, it can trigger tropical convection (e.g., Kiladis and Weickmann, 1992; Waugh and Polvani, 2000).

In the Lagrangian framework, EDIs have been identified as air parcels descending 400 hPa within two days ( $\Delta p \geq 400 \text{ hPa}$  ( $48 \text{ h}$ )<sup>-1</sup>, following Raveh-Rubin, 2017). Using this method, Raveh-Rubin (2017) provided a climatology showing that EDIs are most frequent during boreal winter. They descend nearly adiabatically at 40-50° N following the slanting isentropes towards lower latitudes, experience a decrease in relative humidity on the first day, followed by a moistening due to mixing with planetary boundary layer (PBL) air on the second day, and typically induce low-level instability, wind gusts, intense upward surface latent and sensible heat fluxes, and a deepening of the PBL [recently also found in a study combining observational and reanalysis data by Ilotoviz et al. (2021)]. Distinguishing between trailing cold fronts (connected to an extratropical cyclone) and isolated cold fronts (no cyclone nearby), Catto and Raveh-Rubin (2019) and Raveh-Rubin and Catto (2019) found that trailing fronts match more frequently with EDIs than isolated fronts and suggested that EDIs are essential for the appearance of trailing fronts in the subtropics. Both front types are elongated and strengthened through the deformation flow imposed by the EDI (Catto and Raveh-Rubin, 2019; Raveh-Rubin and Catto, 2019). This strengthening of the fronts, i.e., frontogenesis, can be understood following quasi-geostrophic theory (Davies and Wernli, 2015), if two necessary ingredients are given: a horizontal temperature gradient in combination with a suitably oriented deformation flow. Frontogenesis is associated with an ageostrophic circulation inducing low-level convergence, ascending motion and potentially cloud formation on the front's warm side. The role of convergence lines, in a general sense, has been studied for precipitation in the subtropics (Weller et al., 2017). In our first case study, we illustrate that some of these convergence lines are linked to EDI-related frontogenesis.

After having introduced the EDI, a flow feature from the extratropics, we now turn our attention to tropical convection and how its outflows can affect the trade-wind region in the form of TMDs. The vertical distribution of tropical clouds is known to be tri-modal (Johnson et al., 1999) with deep cumulonimbi reaching up to the tropopause, shallow cumuli being limited in their vertical growth by the trade inversion (up to max 700 hPa, Schubert et al., 1995), and a third maximum in cloudiness emerging near the melting layer (typically around 500-600 hPa, Zuidema, 1998). This layer is often characterized by a stable stratification, capping cumuli congesti and promoting detrainment from cumulonimbi (resulting in so-called shelf-clouds, Johnson et al., 1999). Initial stabilising processes are linked to diabatic warming related to falling ice crystals, which trigger freezing (through contact with supercooled water) above the 0° C isotherm and diabatic cooling due to melting below it (Johnson et al., 1996; Posselt et al., 2008; Stevens et al., 2017). Once the stable layer is established, outflow from cumulonimbi at this level is promoted and the detrained cloud masses exert an overhead radiative cooling, which maintains stability and initiates subsidence. The resulting overturning circulation enhances TMD due to horizontal divergence near the melting layer (Posselt et al., 2008; Stevens et al., 2017). In early studies, additional processes that possibly help to maintain and horizontally expand the stable layer near the melting layer away from the deep convective precipitating system, were mentioned, e.g., the gravity-wave like propagation of a single heating event in a stratified fluid (Mapes, 1993; Mapes and Houze Jr., 1995). In our second case study, we demonstrate how TMD near the melting layer affects the moisture budget of the lower free troposphere in the trade-wind region.

This paper continues with a description of the data and methods (Sect. 2). After an overview of the humidity profiles and transport conditions during the campaign (Sect. 3), the first part of the results focuses on the effect of EDIs on the lower-tropospheric humidity (Sect. 4). The second part looks into the effect TMDs have on the mid-tropospheric humidity over Barbados (Sect. 5). Both parts include a detailed, illustrative case study from EUREC<sup>4</sup>A, which is complemented with a quasi-climatological analysis. The paper ends with a summary and concluding remarks (Sect. 6).

## 2 Data and methods

We use the hourly ERA5 reanalysis data set (Hersbach et al., 2020) on a regular 0.5° × 0.5°-grid to characterise the atmospheric column above Barbados and to compute three-dimensional air parcel backward trajectories from Barbados. For comparison, we consult observational data sets from two sites of the EUREC<sup>4</sup>A experiment. The BCO (<https://barbados.mpimet.mpg.de/>), situated at the east coast of Barbados (13.16° N, 59.43° W, 17 m a.s.l.; Stevens et al., 2016), is operated by the Max Planck Institute for Meteorology, the Caribbean Institute for Meteorology and Hydrology and the Museum of Barbados. From this site, we use the 10 s precipitation measurements taken by the Vaisala WXT-520 meteorological ground station (4 m. a.g.l., Jansen, 2020), the vertical profiles from a Ka-band cloud radar MIRA-36 (11 m. a.g.l.; METEK GmbH; [www.metek.de](http://www.metek.de); hereafter referred to as cloud radar; Stevens et al., 2016), and the data obtained by the Vaisala RS41 radiosondes launched from the BCO (Stephan et al., 2020, typically six radiosondes within 24 h). Data from the Polarization Diversity Doppler Radar (Poldirad; Hagen et al., 2021), deployed by the German Aerospace Center (Deutsches Zentrum für Luft- und Raumfahrt) roughly 8 km west-northwest of the BCO (13.18° N, 59.5° W, 245 m a.s.l.), expand our analysis beyond the location of the BCO. Finally,

images from the MODIS instrument on the satellite Terra provided by the Earth Observing System Data and Information  
 125 System (EOSDIS; <https://wvs.earthdata.nasa.gov>) and from the GOES-16 satellite provided by the GIBBS imagery service  
 (<https://www.ncdc.noaa.gov/gibbs/>; Knapp, 2008) give an overview of the cloudiness on the synoptic scale. In the following,  
 we describe how the local conditions and the transport pathways towards Barbados were characterized.

## 2.1 Characterisation of the local conditions in Barbados

The ERA5 variables are tri-linearly interpolated to a vertical profile (1000-300 hPa, every 7 hPa; Fig. 1a) at the geographical  
 130 location of the BCO every hour in the EUREC<sup>4</sup>A period (16 January to 20 February 2020), and every third hour in the quasi-  
 climatological period (January and February 2010 to 2020). For the case study analyses (Sect. 4 and 5), we average or sum  
 the variables over each day and two vertical layers, namely a lower-tropospheric (1000-650 hPa) and a mid-tropospheric (650-  
 300 hPa) layer. The 24 h time window is chosen because the associated large-scale conditions typically remain similar within  
 one day (Fig. 4). Moreover, the cloud radiative effect should be assessed combining day- and night-time conditions. The two  
 135 vertical layers are defined such that both contain 50 vertical data points and are motivated by the fact that the maximal vertical  
 extent of the low-level cloud layer during the campaign is at about 650 hPa (Fig. 2). This simple definition of temporal and  
 vertical boundaries to obtain a summarizing statistics is also applied at the interannual timescale to investigate the robustness  
 of the identified links between the large-scale circulation and the local conditions. We repeated the above-described steps for  
 four additional points shifted zonally and meridionally from the BCO by 0.5° and found that the results for the five locations  
 140 differ only marginally (not shown). We therefore decide to focus in this study on the profiles directly above the BCO only. The  
 following variables are computed with ERA5 data and partly also with measurements.

**Integrated water vapour (IWV):** We calculate the IWV for the two layers ( $IWV_{1000-650 \text{ hPa}}$ ,  $IWV_{650-300 \text{ hPa}}$ ) using the  
 equation  $IWV_{p_{bottom}-p_{top}} [m] = \frac{1}{g\rho_l} \int_{p_{bottom}}^{p_{top}} q dp$ , with specific humidity ( $q$ ), density of liquid water ( $\rho_l$ ), pressure ( $p$ ), and the  
 gravitational acceleration ( $g$ ). We derive the IWV from ERA5 and the radiosonde measurements (Stephan et al., 2020, 2021).  
 145 Daily mean IWV values are used in both case studies (Sect. 4 and 5).

**Precipitation totals:** ERA5 daily precipitation totals are obtained from adding up convective and large-scale precipitation.  
 Daily precipitation totals are also retrieved from Vaisala WXT-520 measurements (Jansen, 2020) and are used in the overview  
 of the EUREC<sup>4</sup>A period (Sect. 3) and the EDI case study (Sect. 4). Note that a direct comparison between ERA5 precipita-  
 tion values and the measurements is difficult as the former represent averages over a model grid box while the latter yield  
 150 information about the local conditions at the BCO.

**Net cloud radiative effect (CRE):** Following Boucher et al. (2013) and Hartmann (2016), we calculate the net cloud  
 radiative effect (CRE) as the sum of the longwave (LWCRE) and shortwave (SWCRE) cloud radiative effect. The LWCRE  
 results from the difference of the top of atmosphere thermal radiation under clear-sky conditions and the one under cloudy  
 conditions (clear-sky minus cloudy), and analogously for the SWCRE and solar radiation. Using this convention, negative  
 155 values represent a radiative cooling due to the presence of clouds and positive values a warming. As the cloud radiative forcing  
 is very inhomogeneous in space (not shown), an area-weighted mean over the domain 10-20° N, 50-60° W is calculated. The  
 domain's size is chosen similar to Bony et al. (2020), who used 10-20° N, 48-58° W, but here the borders are shifted to the

west to include Barbados. The domain-mean CRE allows a comparison with the results from Bony et al. (2020) and is used in both case studies (Sect. 4 and 5).

## 160 2.2 Characterisation of the transport pathways towards Barbados

Three-dimensional backward trajectories are computed with the Lagrangian analysis tool LAGRANTO (Wernli and Davies, 1997; Sprenger and Wernli, 2015), starting from the interpolation points defined above (Fig. 1b). The calculations are based on the ERA5 wind fields and determine the air parcels' position (longitude, latitude, pressure) during the ten days before arrival. A set of variables is interpolated along the trajectories. We extract each air parcel's position four days before arrival (Fig. 4; 165 see Fig. S1.1 and S1.2 in Supplement 1 for other time steps) to get an impression of the pathway variability across the vertical profile and during the EUREC<sup>4</sup>A time period. The choice of four days is inspired by the study of Aemisegger et al. (2021), who showed that the transport during this pre-arrival time window is essential for understanding moisture anomalies induced by the large-scale circulation in the trades. Typically, multiple airstreams (coherent bundles of trajectories with similar characteristics) arrive in each of the two layers during 24 h. For each airstream, defined in Sect. 4.2 and 5.2, we compute the mean specific 170 humidity (per air parcel) and the contribution to the IWV of the arrival layer (Table 1 and 4).

## 3 Temporal evolution of the atmospheric column above Barbados during EUREC<sup>4</sup>A

In this section, we present the humidity, wind, radiative and transport conditions over Barbados during EUREC<sup>4</sup>A. Throughout the campaign, the Eulerian (Fig. 2 and 3) and the Lagrangian (Fig. 4) conditions varied substantially in the lower and middle troposphere. The clouds over the BCO can be identified from contours of liquid water content and were generally associated 175 with localised positive anomalies in specific humidity (Fig. 2a). The cloud tops were typically below 700 hPa but occasionally reached 600 hPa, namely on 22-24 January, 11-13 February and 18-19 February. The extended cloud layers led to elevated values of  $IWV_{1000-650 \text{ hPa}}$  (Fig. 3a) and precipitation totals (Fig. 3b), whereof the most persistent rain event took place on 22 January. The daily mean cloud radiative cooling (Fig. 3c) was comparably strong during these three periods (about  $-29$  to  $-45 \text{ W m}^{-2}$  compared to a campaign-mean value of  $-21 \text{ W m}^{-2}$ ).

180 Towards the end of the campaign, a persistent mixed-phase cloud layer (Fig. 2a) appeared at mid-tropospheric levels leading to a positive anomaly in  $IWV_{650-300 \text{ hPa}}$  (Fig. 3a) with dry conditions below. This mid-tropospheric cloud provoked an immediate response in the CRE (Fig. 3c) with stronger warming/cooling during nighttime/daytime (local time in Barbados corresponds to UTC-4 h), leading to a daily mean CRE of  $-79 \text{ W m}^{-2}$  on 14 February, the most negative value during the campaign. On 15 February, however, the warming almost completely balanced the cooling such that the daily mean CRE matched the campaign 185 mean value.

The local wind conditions indicate periods with different strength of the prevailing low-level easterlies (Fig. 2b). From 25 January to 4 February the low-level easterlies were weak, followed by a period with strong easterlies until 20 February. At mid-tropospheric levels, northwesterlies dominated, except for 12-16 February, when the mixed-phase cloud layer advected from the south was present. Overall, weak downward vertical winds were observed (Fig. 2c). At low levels, upward motion associated

190 with convective cells and rain water content, e.g., on 22 January, alternated with downward motion in downdrafts. On 12-16 February, unusually pronounced upward winds above approximately 550 hPa occurred together with enhanced subsidence below.

The distance the air parcels traveled within the four days before arrival (Fig. 4a) shows similar variability patterns as the local horizontal winds (Fig. 2b and c), including periods with close to stationary transport conditions within the last days prior to arrival and periods with pronounced long-range transport exceeding 5000 km in four days. At upper levels, the air parcels generally traveled long distances, except when they were advected from the tropics (12-16 February, Fig. 4b). At low levels, weak local easterlies (Fig. 2b) coincided with short-range transport and strong easterlies with long-range transport (Fig. 4a). One exception can be found around 22 January, when long-range transport is observed at low levels, even though the local easterlies are not particularly strong. These air parcels originated from high latitudes (Fig. 4b) and descended rapidly (Fig. 4c) until reaching the BCO. On 8 February, another (less coherent) descending airstream from the extratropics arrived in Barbados. Otherwise, the air parcels moved within the subtropics or tropics (Fig. 4b) and subsided at a moderate rate corresponding to the expected values from the balance between adiabatic compression and radiative cooling (Fig. 4c).

Based on the descriptions above, the typical trade-wind conditions (26 January to 7 February) with slow descending motion and weak horizontal transport in the lower free troposphere combined with low-level easterlies (Hadley-like circulation) are associated with a relatively moist well-mixed sub-cloud layer, a shallow cloud layer (950-750 hPa), and a strong inversion associated with very dry conditions (at 700 to 800 hPa). These typical trade wind conditions are interrupted during two periods (indicated by the red rectangles or shading in Fig. 2-4) associated with strong positive anomalies in specific humidity (also in relative humidity, Fig. S1.3 in Supplement 1) and precipitation totals (22 January) as well as negative anomalies in the CRE. These two periods are particularly striking in terms of transport. First, the lower-tropospheric moist anomaly on 22 January, which is related to long-range transport from the upper-level extratropics. Second, the mid-tropospheric moist anomaly on 14 February, which is linked to quasi-horizontal short-range transport from the tropics. In the following Sect. 4 and 5, we have a closer look at these two events, in particular, the air parcel transport histories, to understand the formation of the local anomalies.

#### 4 Case study about the link between EDIs and low-level moist anomalies in the trades

215 This section illustrates how an EDI and its interaction with a trailing cold front induces the lower-tropospheric moist anomaly over Barbados on 22 January 2020. First, we present the Eulerian characteristics of the event (Sect. 4.1), followed by the Lagrangian analysis (Sect. 4.2). In order to put the case study results in a broader context, results from a quasi-climatological assessment of EDI events in Barbados are discussed in Sect. 4.3.

##### 4.1 The impact of a trailing cold front on the trade-wind region

220 On 22 January 2020, a trailing cold front, visible as a cloud band loosely connected to a cyclone over the subtropical North Atlantic (Fig. 5a), reached Barbados. The resulting mesoscale cloud organisation in the vicinity of the island can be described as

cloud bands typical for the Fish cloud pattern following the classification of Stevens et al. (2020). The Fish cloud broke up into smaller fragments the day after its passage over Barbados, while travelling further into the tropics (not shown). On 22 January 2020, a saturated layer developed in the early morning near 800 hPa, which grew vertically up to 600 hPa at the expense of the dry air aloft, as can be seen in the profiles from the balloon soundings (Fig. 5b) and the cloud radar's measurements (Fig. 5c). The precipitating humid layer persisted until shortly before local midday (confirmed by personal observation on-site).

The lower-tropospheric moist layer, formed by the passage of the cold front on 22 January 2020, can be clearly identified as strongly anomalous compared to the rest of the campaign in the daily mean  $IWV_{1000-650 \text{ hPa}}$  (Fig. 6a). The cold front led to prolonged precipitation periods in Barbados such that the precipitation total on 22 January 2020 is also strongly anomalous compared to the rest of the campaign (Fig. 6b). This is consistent with the study by Schulz et al. (2021), who showed that Fish clouds are associated with high rain amounts, but not necessarily high rain rates. Both anomalies,  $IWV_{1000-650 \text{ hPa}}$  and precipitation totals, are more pronounced in the measurements than in ERA5 (Fig. 6a,b).

The Fish cloud had a net cooling effect over Barbados in the daily mean (Fig. 6c), leading to strongly negative CRE values of about  $-38 \text{ W m}^{-2}$  on 22 January 2020. This reflects that the cooling shortwave effect during daytime dominated the continuous but comparably weak warming longwave effect (Fig. 3). Note that this effect is spatially confined to the cloud band. If averaged over a  $10^\circ \times 10^\circ$  domain ( $10\text{--}20^\circ \text{ N}$ ,  $60\text{--}50^\circ \text{ W}$ ; red box in Fig. 5a), the CRE on 22 January 2020 reduces to values of about  $-27 \text{ W m}^{-2}$ , which however is still anomalously negative compared to the rest of the campaign (Fig. 6c). Generally, ERA5 shows 10 to  $20 \text{ W m}^{-2}$  more negative net cooling over the  $10^\circ \times 10^\circ$  domain compared to the satellite-based study of Bony et al. (2020, their Fig. 5). Deviations of a similar magnitude have been found in other studies comparing the CRE derived from reanalysis data to satellite-based products (Fig. 3 and 4 in Joos, 2019).

In the next subsection, we discuss to what extent the cold front's movement into the tropics, and the associated EDI, contribute to the above described anomalous local conditions.

## 4.2 Descent from the extratropical upper troposphere into the trade-wind cloud layer

The trajectories leading into the anomalously moist layer (1000-650 hPa) over the BCO on 22 January 2020 (Fig. 7) can be bundled into five coherent airstreams. To assess these airstreams, we first identify the trajectories with a strong descent and assign them to three EDI airstreams (the leading L in the airstreams' names stands for the arrival in the lower troposphere):

- **L-EDIwcb**: Trajectories with a strong EDI descent ( $\geq 400 \text{ hPa} (48 \text{ h})^{-1}$ ), which also experienced a warm conveyor belt (WCB)-like ascent ( $\geq 600 \text{ hPa} (48 \text{ h})^{-1}$ ; following Wernli, 1997) from the lowermost to the upper troposphere prior to the EDI descent, identified during the ten days before arrival.
- **L-EDIs**: Trajectories with a strong EDI descent ( $\geq 400 \text{ hPa} (48 \text{ h})^{-1}$ ) within ten days before arrival, but no previous WCB-like ascent.
- **L-EDIw**: Trajectories with a weak EDI descent ( $\geq 300 \text{ hPa} (48 \text{ h})^{-1}$ ) within ten days prior to arrival.

The remaining trajectories are divided into two airstreams depending on whether they entered the lower troposphere from above or were already in it during the five days before arrival:

- 255 – **L-MT**: Trajectories that descend from the mid-tropospheric layer into the lower-tropospheric layer (at a lower rate than the EDI-airstreams) during the five days before arrival.
- **L-LT**: Trajectories that remain in the lower-tropospheric layer during the five days before arrival.

Overall, the transport into Barbados' lower troposphere on 22 January 2020 was influenced by an extratropical upper-level Rossby wave breaking over the central North Atlantic roughly four days earlier (Fig. 7, Fig. S2.4 in Supplement 2 and animation in Supplement 3), associated with an upper-level PV streamer (red contour in Fig. 7) and an intense surface cyclone underneath (black contour in Fig. 7, using the detection method of Wernli and Schwerz, 2006). A region of dynamically driven large-scale subsidence is found upstream of the PV-streamer (Fig. 7a-c), as expected from quasi-geostrophic theory (Davies and Wernli, 2015). From 17-19 January 2020, the three L-EDI airstreams (L-EDI<sub>wcb</sub>, L-EDIs, and L-EDI<sub>w</sub>; brown upward-/downward-facing triangles and diamonds in Fig. 7; brown lines in Fig. 8) were steered into this region at upper levels ( $p \sim 500$  hPa) and rapidly descended into the cold sector of the extratropical cyclone (Fig. 8a) where they met the L-LT airstream (green left-facing triangles in Fig. 7a).

The descent caused a massive decrease in relative humidity along the trajectories (Fig. 8c), as the L-EDI air parcels were adiabatically warmed while staying dry (Fig. 8f) reflecting limited mixing with the environment. Simultaneously, ocean evaporation beneath the L-EDI air parcels was reinforced (blue contours in Fig. 7b; Fig. 8d). On 20 January 2020 the EDI-like descent was completed and the L-EDI penetrated the cloud layer, which is marked by a sudden increase in relative humidity (Fig. 8c) and liquid water content (Fig. 8e). Once the airstream arrived in the sub-cloud layer, the specific humidity continued to increase (Fig. 8f), while the liquid water content decreased (Fig. 8e), which likely contributed to the L-EDI air parcels' moistening through hydrometeor evaporation. The enhanced surface evaporation setting in with the EDI's descent (resulting from the advection of dry unsaturated air over the ocean surface, e.g., Aemisegger and Papritz, 2018) and the subsequent increase in specific humidity approximately 24 h later is typical for EDIs over the North Atlantic (Raveh-Rubin, 2017, their Fig. 8 and 11).

The L-LT air parcels (remaining in the lower-tropospheric layer during the five days before arrival) moved towards lower latitudes along the western edge of the surface cyclone (Fig. 7a) while slightly descending (green line in Fig. 8a). They experienced a gradual increase in relative (green line in Fig. 8c) and specific humidity (Fig. 8f), which set in earlier than for the L-EDI airstreams. On 19-20 January 2020, the L-LT's moistening (Fig. 8f) temporarily flattened due to mixing with the L-EDI airstreams. At the same time, the PV streamer broke up and a PV cutoff formed northeast of Barbados (Fig. 7c-d). The low-level cyclonic circulation induced by the PV cutoff pushed the L-LT and the L-EDI air parcels (located west of the cutoff) southwards (Fig. 7d). While further descending, the L-LT and L-EDI air parcels caught up with the cold front. The cold front is identifiable in a region with a strong horizontal gradient in equivalent potential temperature (Fig. S2.4 in Supplement 2) behind a line of high total column water (Fig. 7b-d), which is associated with low-level convergence and precipitation (Fig. S2.4 in Supplement 2). At roughly 20° N, the L-LT and L-EDI air parcels entered the trade-wind region and eventually reached Barbados at low levels (1000-650 hPa).

The remaining L-MT air parcels (slowly descending from above 650 hPa) moved predominantly within tropical latitudes (purple line in Fig. 8b) and descended moderately (Fig. 8a), following a typical Hadley-type transport pathway. This airstream arrived at the top of the lower troposphere in the region of the inversion and most likely mixed only marginally with the cloud layer air, as shown by the low values in liquid water content (Fig. 8e) and specific humidity (Fig. 8f).

In summary, 45 % of the 1200 air parcels arriving between 1000 and 650 hPa on 22 January 2020 belong to the L-EDI airstreams (Table 1), contributing to 58 % of the  $IWV_{1000-650 \text{ hPa}}$ . The L-LT contains 20 % of the trajectories and makes up 26 % of the  $IWV_{1000-650 \text{ hPa}}$  (Table 1). Lastly, L-MT holds 35 % of the trajectories, which contributes 16 % of the  $IWV_{1000-650 \text{ hPa}}$  (Table 1). Thus, we conclude that the EDI air parcels were the key players in the formation of the low-tropospheric moist anomaly on 22 January 2020.

### 4.3 The climatological relevance of EDIs for the environmental conditions in the trades

In the following, we assess how frequently EDIs occur in general and how often they are related to local conditions similar to the ones on 22 January 2020. For this, we extract all EDI days from the 11 Januaries and Februaries 2010-2020 (quasi-climatological period). The remaining days are referred to as nonEDI days. An EDI day is identified if at least 5% of the trajectories arriving from 00 to 23 UTC between 1000 and 650 hPa over the BCO descended 400 hPa  $(48 \text{ h})^{-1}$  within the four days prior to arrival. The considered time span of four days ensures that only EDIs subsiding over the North Atlantic (corresponding to the extratropical dry intrusion regime in Aemisegger et al. (2021), their Fig. 3a) and not over Europe/Africa (corresponding to the extratropical trade-wind regime in Aemisegger et al. (2021), their Fig. 3b) are selected. Typically, air parcels from the extratropical trade-wind regime require about six days to traverse the North Atlantic. The selection criterion is subjectively chosen but ensures that the well-documented EDI cases on 22 January 2020 and on 31 January 2018<sup>1</sup> are included.

Applying this criterion, we find that EDIs arriving at Barbados are comparatively rare. Only 44 (~7%) of the total 652 days in the quasi-climatological period are identified as EDI days (Table 2). The local conditions at the BCO on EDI days range from extremely dry with no precipitation to extremely moist with high precipitation totals and varying CRE (Fig. 9). In the considered period, EDIs occur on six (18 %) of the 33 driest days according to  $IWV_{1000-650 \text{ hPa}}$ , on eight (24 %) of the 33 wettest days according to total precipitation, and on seven (21 %) of the 33 days with the lowest CRE. Other (presumably local) processes are responsible for the rest of the three variables' extremes. Thus, even though EDIs arriving in Barbados are relatively rare, they can trigger extremes of either sign in  $IWV_{1000-650 \text{ hPa}}$ , and they occur in connection with heavy precipitation and anomalously low CRE more frequently than their climatological occurrence frequency indicates.

On EDI days, the two variables,  $IWV_{1000-650 \text{ hPa}}$  and precipitation totals, are more strongly positively correlated than on nonEDI days (Table 3). The relation between CRE and precipitation or  $IWV_{1000-650 \text{ hPa}}$  is only marginally stronger on EDI days than on nonEDI days. Nevertheless, we observe a shift towards lower daily mean CRE values on EDI days (with a mean of  $-28 \text{ W m}^{-2}$ ) compared to nonEDI days (with a mean of  $-18 \text{ W m}^{-2}$ ). Especially the EDIs with extremely high  $IWV_{1000-650 \text{ hPa}}$  and daily precipitation totals (in the upper right corner of Fig. 9a,b), consistently have an enhanced cloud radiative cooling. Two processes in connection with EDIs contribute to a strengthening of the cloud radiative cooling. Due to the

<sup>1</sup>Here we only identify the onset of this event because of using a slightly different EDI selection criterion and a smaller set of trajectories.

EDI's subsidence we expect an anomalously dry free troposphere (no mid-/upper-level clouds), which strengthens the long-wave radiative cooling (Cau et al., 2007) and explains low CRE on days with a dry lower troposphere. Additionally, the EDI can be associated with a Fish cloud (as on 22 January 2020), which strengthens the shortwave radiative cooling (Bony et al., 2020) and leads to low CRE on days with a moist lower troposphere. Anomalously high CRE on EDI days are most likely  
325 caused by other processes higher up in the atmosphere such as cirrus clouds, which affect CRE but have no impact on the low-level variables. These overall stronger links between precipitation,  $IWV_{1000-650\text{ hPa}}$  and CRE emerge due to the large-scale nature of the perturbations induced by EDIs.

We assume that the difference between the extremely moist and wet EDIs (in the upper right corner of Fig. 9a,b) and the remaining EDIs arises from mesoscale details of how the EDIs modulate the dynamical properties of the associated trailing  
330 cold fronts, which can be best described by the low-level divergence in the region of Barbados (Fig. 9b). As we know from theory, a frontogenetic front is characterised by a strong dipole in low-level divergence associated with the frontal ageostrophic circulation. Behind the cold front, namely in the cold sector in which the EDI spreads out, low-level divergence dominates. Thus, a strongly negative daily mean divergence (i.e., convergence) on an EDI day possibly indicates that Barbados was heavily influenced by the front's warm side, while a strongly positive value hints towards a prolonged influence of the front's cold side  
335 and the following cold sector. To test this hypothesis, we study the transport history of the five EDIs with the most negative and the most positive low-level divergence, referred to as  $EDI_{con}$  and  $EDI_{div}$ , respectively (Fig. 10, listed in Table 2) and the synoptic situation of the two most extreme cases (Fig. 11).

$EDI_{con}$  trajectories descend strongly (Fig. 10a), reach cloud tops 2-3 days before arrival (peak in liquid water content, Fig. 10c), dive into the boundary layer, and experience an important increase in liquid water content when passing through  
340 the front and ascending again on the warm side one day before arrival. Due to their closeness to the surface,  $EDI_{con}$  trajectories efficiently trigger ocean evaporation (Fig. 10b), which contributes to a rapid increase in specific humidity (Fig. 10d). Unlike  $EDI_{con}$ ,  $EDI_{div}$  trajectories show a slowdown of the descent when reaching  $\sim 800\text{ hPa}$  (Fig. 10a). From then on liquid water content remains high (Fig. 10c), suggesting that the trajectories stay in clouds and do not reach the sub-cloud layer. Consequently,  $EDI_{div}$  trajectories are associated with lower values of surface evaporation (Fig. 10b) and specific humidity (Fig. 10d) than  
345  $EDI_{con}$ . The synoptic situations on the EDI day with the lowest and highest low-level divergence confirm the above described mechanisms.

**Strongest  $EDI_{con}$  event:** An event in the  $EDI_{con}$  category with strong low-level convergence ahead of a frontogenetic cold front occurred on 27 January 2010 with the following characteristics: divergence =  $-15.8 \cdot 10^{-6}\text{ s}^{-1}$ ,  $IWV_{1000-650\text{ hPa}}$  = 33.8 mm, precipitation = 3.2 mm, and CRE =  $-29.8\text{ W m}^{-2}$ . At 12 UTC 27 January 2010, Barbados was located on the  
350 warm side of the cold front in a region of strong low-level convergence (Fig. 11a). The red thick contours in Fig. 11a show ERA-Interim fronts identified with a horizontal gradient in equivalent potential temperature at 850 hPa larger than  $3.5\text{ K (100 km)}^{-1}$  (Schemm et al., 2015). The EDI air parcels in this case moved from the cold sector through the front, most likely due to the ageostrophic circulation associated with the front. This idea is supported by the Q-vectors (arrows in Fig. 11a) which point from low to high equivalent potential temperature near the front, indicating frontogenesis, as expected (see introduction) when  
355 a deformation flow (the EDI) acts on a horizontal temperature gradient (the front). Consequently, the ageostrophic circulation

at the front is upheld (shown by the neighbouring bands of low-level divergence and convergence in Fig. 11b; note that a different pressure level is shown than in Fig. 11a to enable a direct comparison to Schulz et al., 2021) while it passes Barbados. The dynamics of the front directly impacts the observed local conditions. The low-level convergence leads to an accumulation of moisture increasing the  $IWV_{1000-650 \text{ hPa}}$  value. The ascending motion on the front's warm side promotes cloud formation reducing the shortwave radiative input and potentially initiating precipitation. Strong convergence at 950 hPa was previously linked to the Fish cloud pattern (Schulz et al., 2021) and thus to strong cloud radiative cooling (Bony et al., 2020). Indeed, we find a distinct cloud band directly over/close to Barbados on the five considered  $EDI_{\text{con}}$  days (exemplary cases in Fig. S2.1 in Supplement 2).

**Strongest  $EDI_{\text{div}}$  event:** An event in the  $EDI_{\text{div}}$  category with low-level divergence behind the cold front occurred on 3 February 2013 with the following characteristics: divergence =  $22.4 \cdot 10^{-6} \text{ s}^{-1}$ ,  $IWV_{1000-650 \text{ hPa}} = 19.2 \text{ mm}$ , precipitation = 0 mm, and CRE =  $-0.8 \text{ W m}^{-2}$ . At 06 UTC 3 February 2013 (Fig. 11c), the island was located in the cold sector behind a cold front (Fig. 11c) in an environment of strong low-level divergence (Fig. 11d) leading to the exact opposite characteristics than on 27 January 2010, i.e., low  $IWV_{1000-650 \text{ hPa}}$ , cloud-free conditions and no precipitation. However, it would be misleading to relate EDIs arriving together with the cold sector exclusively to cloud-free conditions. Often the cold sector features typical open or closed convection cells (e.g., Krueger and Fritz, 1961; Agee et al., 1973, exemplary cases in Fig. S2.2 in Supplement 2), which might further explain the large variability of CRE on EDI days.

The main difference between events in the  $EDI_{\text{con}}$  and  $EDI_{\text{div}}$  categories is the relationship between the cold front and the EDI. In the first case, the EDI overtakes the cold front. In the second case, the front and the EDI are spatially and temporally separated, with the front propagating faster than the EDI. However, the fact that the EDI catches up with the cold front is not sufficient for wet conditions to arise. We found at least one case on 31 January 2018 (discussed in Aemisegger et al., 2021), when the EDI air parcels arrive in Barbados together with the warm air ahead of the cold front, but the distinct dipole structure of low-level divergence at the front had already dissolved (front in a frontolytic state). A plausible cause for these contrasting situations is the upper-level forcing and the corresponding strength of the surface cyclone which is notably stronger for  $EDI_{\text{con}}$  days than for  $EDI_{\text{div}}$  (Fig. 11, Fig. S2.3 in Supplement 2) and therefore supports the stronger deformation and frontogenesis.

Overall, we demonstrated that EDIs descending from the midlatitude jet stream region into low latitudes disturb the trade-wind region's environmental conditions such as CRE, precipitation and  $IWV_{1000-650 \text{ hPa}}$ . If the EDI catches up with the cold front, this can lead to a low-tropospheric moist anomaly, the occurrence of the Fish cloud pattern and enhanced radiative cooling. Due to their large-scale flow forcing, EDIs are good candidates for studying the cloud-circulation coupling in detail also in coarse resolution ( $0.5\text{-}1^\circ$  horizontal grid spacing) climate simulations.

A follow-up study will look into the EDI's interaction with the cumulus cloud deck of the marine boundary layer behind the cold front and the environment in which EDI trajectories penetrate through the cloud-capping inversion. Furthermore, the interaction between the cold front and the EDI should be studied on a process level to understand whether the EDI is critical for the propagation of the front and the cold sector into the tropics. For this, it would be insightful to adopt a front-centered perspective by comparing fronts appearing as individual features to fronts which occur together with an EDI. Previous knowledge on this topic exists. Catto and Raveh-Rubin (2019) found that trailing cold fronts at low latitudes in most cases

coincide with EDIs. Raveh-Rubin and Catto (2019) showed that EDIs significantly influence the characteristics of the fronts and their surroundings. Lastly, Esler et al. (2003) suggested a link between the surface cyclone's strength and the EDI's penetration depth into the boundary layer and degree of moistening. Additional insights could be gained from the analysis of stable water isotopes which provide information about moisture cycling in frontal regions (Aemisegger et al., 2015; Graf et al., 2019). Expanding the analysis beyond the geographical location of Barbados and the two months of the EUREC<sup>4</sup>A experiment would increase the number of EDIs and thereby further advance our understanding of their impact on the trade-wind region.

## 5 Case study about the link between TMDs and mid-level moist anomalies in the trades

In this section we analyse an event with TMD (tropical mid-level detrainment) near the melting layer that leads to the mid-tropospheric moist anomaly over Barbados on 14 and 15 February 2020 (Fig. 2a). Similar to the first case study, we first discuss the Eulerian (Sect. 5.1) and Lagrangian (Sect. 5.2) characteristics of the event, followed by a quasi-climatological assessment of tropical detrainment at mid (TMDs) and upper (TUDs) levels affecting Barbados (Sect. 5.3).

### 5.1 The impact of a mixed-phase shelf cloud on the trade-wind region

On 14 February 2020, Barbados was covered by a mid-tropospheric shelf cloud detrained from cumulonimbi over South America (shown in Sect. 5.2) forming a large-scale nearly closed altocumulus layer extending from 5° N over South America northwards to about 18° N (Fig. 12a). The large-scale dimension of the mid-level cloud layer is emphasized in the Poldirad cross section (Fig. 12d), where it spans the full width of 120 km. The shelf cloud persisted throughout 14 and 15 February and dissipated on 16 February 2020 (not shown). The saturated layer associated with these mixed-phase clouds (Fig. 13b) was relatively deep and extended between the 0° C isotherm near 600 hPa and 300 hPa at −30° C (Fig. 12b). A distinct dry layer separated the shelf cloud from the shallow trade-wind cumuli beneath (Fig. 12b-d). This dry layer was moistened through the evaporation of hydrometeors falling from the shelf cloud. In some cases the precipitation reached the surface, e.g., 20 km away from the Poldirad (Fig. 12d). In other cases it completely evaporated, as shown in the cloud radar image (Fig. 12c) in the form of downward propagating reflectivity signals that, however, do not reach the shallow trade-wind cumuli.

We assume that this moistening process created favorable conditions for the vertical growth of shallow convection beneath. Indeed, individual convective cells penetrating the dry layer from below are visible from the large radar reflectivity values in the two radar images, e.g., after 20 UTC above Barbados (Fig. 12c) and about an hour earlier between 80 and 85 km away from the Poldirad (Fig. 12d). In these situations enhanced shallow convection injected moisture upward into the shelf cloud, potentially contributing to the persistence and considerable northward extension of this layer. At least in two cases, at 08 and 14 UTC, such a convective cell pushing through the trade inversion was observed shortly after a moistening event of the dry layer by evaporation of hydrometeors falling out of the altocumulus layer (Fig. 12c). This temporal succession suggests that evaporatively driven downdrafts might have acted as an initiating process for more vigorous shallow convection at low levels (e.g., Zuidema et al., 2012; Li et al., 2014; Vogel et al., 2016). However, we cannot distinguish between the temporal evolution and the advection of clouds (low-level easterlies and mid-level southerlies, Fig. 12b) in the images from the vertically

pointing cloud radar (Fig. 12c). Thus, mid- and low-level features that appear in close temporal succession are not necessarily causally linked. The complex interaction between the two cloud layers and the separating dry layer remains to be disentangled. Potentially stable water isotopes could help to understand the involved moist processes (e.g., Noone et al., 2011; Bailey et al., 2015; Torri et al., 2017; Risi et al., 2019, 2020).

Above Barbados, the shelf cloud caused a positive anomaly in the daily mean of the  $IWV_{650-300 \text{ hPa}}$  (rhombus in Fig. 13a) and the total column ice water (Fig. 13b) compared to the remaining campaign days, which led to enhanced cloud radiative cooling above Barbados ( $-79 \text{ W m}^{-2}$ ) and over the  $10^\circ \times 10^\circ$  domain ( $-34 \text{ W m}^{-2}$ ) on 14 February 2020 (Fig. 13c). On the following day we find similar contents of water vapour and total column ice water (square in Fig. 13a,b), albeit with a reduced cloud radiative cooling ( $-21 \text{ W m}^{-2}$  over the BCO and  $-12 \text{ W m}^{-2}$  over the  $10^\circ \times 10^\circ$  domain) comparable to the campaign mean value (Fig. 13c). The reduced cloud radiative cooling on 15 February 2020 compared to the previous day might be an effect of the 24h averaging. Additionally, given the sensitivity of the CRE of mixed-phase clouds to the ice-liquid ratio and to the ice crystals' size and shape (e.g., Sun and Shine, 1994; Storelvmo et al., 2011; Tan et al., 2016), the microphysical properties of the cloud layer might also contribute to the differences in the cloud radiative forcing on the two days. In the following subsection, we examine the transport history of the air parcels that arrive at mid-tropospheric levels and outline the role of tropical dynamics.

## 5.2 Ascent in the ITCZ and detrainment into the trade-wind lower free troposphere

The air parcels that arrived in Barbados in the mid-tropospheric layer (650-300 hPa) on 14 February 2020 originate from different, mainly tropical and subtropical locations (Fig. 14a). To identify the pathways that eventually led to the moist anomaly, we define four airstreams based on the trajectories' pressure evolution (each trajectory is assigned to one airstream only and the leading M in the airstreams' names stands for the arrival in the middle troposphere):

- **M-trades**: Trajectories that enter the mid-tropospheric layer from below.
- **M-local**: Trajectories that remain in the mid-tropospheric layer in the ten days before arrival.
- **M-UT1**: Trajectories that cross the mid-tropospheric layer from below and re-enter it from above.
- **M-UT2**: Trajectories that enter the mid-tropospheric layer from above.

The M-trades air parcels started their journey near the African West coast (green left-facing triangles in Fig. 14a) and crossed the North Atlantic along the southern edge of a persistent anticyclone, centred at roughly  $30^\circ \text{ N}$ . They travelled at low altitudes until reaching South America (Fig. 14b), where they rapidly ascended (green line in Fig. 15a) in deep convective systems associated with the ITCZ (shown by the low cloud temperatures in Fig. 14d). The ascent is associated with a drop in specific humidity (Fig. 15e), resulting from cloud formation. Near the melting layer (red dashed line in Fig. 16), the air parcels were detrained and spread northwards embedded in a developing shelf cloud (Fig. 16a). At the cloud's northern tip, some air parcels left the cloud and penetrated the dry layer beneath (Fig. 16b), presumably due to the subsidence induced by radiative cooling (Stevens et al., 2017, their Fig. 16). Consequently, the airstream's liquid water content temporarily decreased (Fig. 15c) until

clouds formed again due to the outflow from cumuli congesti over South America on 12 February 2020 (Fig. 15c, 16c). The specific humidity remained largely unaffected by this process (Fig. 15e). However, these nearly constant values of specific humidity became increasingly anomalous as the M-trades airstream moved northwards into climatologically drier regions (Fig. 15f).

Shortly before arrival in Barbados, ice (Fig. 16d) and snow formed likely due to ascent along the slightly tilted isentropes. The air parcels ascended well above the  $0^{\circ}\text{C}$  isotherm, which might have initiated heterogeneous freezing (Fig. 16d; by meridionally shifting the vertical cross section (not shown), we checked that the cloud is a large-scale shelf cloud and not just the upper part of a tilted deep convective tower which intersects the cross section). Simultaneously, the cloud was precipitating into the dry layer beneath (blue dashed contours in Fig. 16d). The distinct pattern of strong downward winds (orange contours in Fig. 16d, already noted in Fig. 2c) below a precipitating cloud points towards evaporatively driven downdrafts, supporting the hypothesis formulated in Sect. 5.1.

The M-local airstream was already located over South America in the mid-tropospheric layer ten days prior to its arrival (purple right-facing triangles in Fig. 14a). Around 10 February 2020, M-local merged with M-trades (green and purple lines in Fig. 15a,b). After that, the two airstreams show very similar transport histories and therefore we refer back to the detailed description in the preceding paragraphs. Together, M-local and M-trades contain 76 % of the air parcels that arrive at mid-tropospheric levels on 14 February 2020 and brought 93 % of the  $\text{IWV}_{650-300\text{ hPa}}$  (Table 4).

Therefore, the remaining airstreams (M-UT1, M-UT2) only contributed little in terms of air parcels and moisture content (Table 4). The few M-UT1 air parcels rose over the eastern Pacific (light brown upward-facing triangles in Fig. 14) from 8-10 February 2020 (light brown line in Fig. 15a). The rapid ascent brought them to subtropical latitudes (Fig. 15b) and resulted in a substantial decrease in specific humidity (Fig. 15e). When the M-UL1 airstream finally arrived in Barbados, it had dried out almost completely (Table 4, Fig. 15e).

The M-UL2 airstream exited the subtropical jet and approached from upper levels slightly north of Barbados or featured a Hadley cell-like descent at tropical latitudes (dark brown downward-facing triangles in Fig. 14). The trajectories in the subtropical jet completed almost a full circle around the globe within ten days, starting their journey over continental North Africa (Fig. 14a). As M-UL2 stayed at upper levels (dark brown line in Fig. 15a), its water content (Fig. 15c-e) remained close to zero throughout the ten days. M-UL1 and M-UL2 make up 24 % of the air parcels and hold 7 % of the  $\text{IWV}_{650-300\text{ hPa}}$  (Table 4). Thus, even though the two airstreams happened to arrive in the mid-tropospheric layer on 14 February 2020, they were not relevant for the observed moist anomaly. In other words, the mid-level moist anomaly above Barbados was essentially produced by outflow from the tropical shelf cloud, which was fed by airstreams from the North Atlantic trades and tropical South America.

### 5.3 The climatological relevance of TMDs for the environmental conditions in the trades

The characteristic feature of the most relevant airstream (M-trades) involved in the formation of the mid-tropospheric moist anomaly above Barbados on 14 February 2020 is the ascent within a convective system over South America and the subsequent detrainment. To assess the importance of this transport pathway, we select all days from the quasi-climatological period on

which at least 15 % of the trajectories arriving 00-23 UTC between 650 and 300 hPa over the BCO travelled to the southern hemisphere (minimal latitude  $< 0^\circ$  N) and ascended from the lower troposphere (maximal pressure  $> 650$  hPa) within the ten days before arrival. To account for the relevance of the detrainment height, these days are further stratified according to the minimal pressure along the trajectories. This stratification reveals a clear separation between TMD and TUD at 400 hPa (Fig. 17). The criteria for the selection and the categorization are subjective, but serve the purpose to identify days with a transport history similar to 14 February 2020. Note that the demanded percentage of trajectories meeting the criteria for a tropical detrainment day is higher than for an EDI day (Sect. 4.3), because the M-trades airstream in Sect. 5.2 contained more trajectories than the L-EDI airstreams in Sect. 4.2.

Applying this definition, we identify 29 days ( $\sim 4\%$ ) with tropical detrainment, whereof 20 classify as TUD and nine as TMD (Table 5). Tropical detrainment often occurs on several consecutive days, meaning that the identified days originate from a few events only. All TMDs lead to an anomalously moist middle troposphere above Barbados, occasionally associated with the formation of ice crystals (Fig. 17). Eight (24 %) of the TMDs belong to the 33 days with the highest values of  $IWV_{650-300 \text{ hPa}}$  (Fig. 17a) and five TMDs as well as one TUD (18 %) to the 33 days with the highest total column ice water content (Fig. 17b). It appears that the mid-tropospheric humidity conditions do not strongly influence the CRE over Barbados (Fig. 17a, Table 6). Thus, the case observed on 14 February 2020 during EUREC<sup>4</sup>A represents a very rare outlier with a CRE of  $-79 \text{ W m}^{-2}$ .

The distinction between TUDs and TMDs highlights the importance of the detrainment height for the humidity conditions at the air parcels' arrival over Barbados (note the high correlation between  $IWV_{650-300 \text{ hPa}}$  and the minimal pressure in Table 6). Both pathways, TMD and TUD, start in the tropics (Fig. 18c) at low altitudes (Fig. 18a). On TUD days, the air parcels ascend to upper levels (Fig. 18a), losing nearly all moisture (Fig. 18b) and liquid water (Fig. 18d) before returning to mid-tropospheric levels. On TMD days, on the contrary, the air parcels stop their ascent at around 500 hPa and subsequently move north (Fig. 18c) on a roughly constant pressure (Fig. 18a) and temperature (not shown) surface. They stay in clouds (Fig. 18d) and lose only little moisture (Fig. 18b), and eventually cause a strong moist anomaly over Barbados.

The quasi-climatological analysis linked tropical detrainment to mid-tropospheric moist anomalies above Barbados. We established a strong relation between the detrainment height and the magnitude of the moist anomaly. However, the amount of water vapour between 650 and 300 hPa appeared at large to be unrelated to CRE. Similar to the quasi-climatological analysis of EDIs (Sect. 4.3), the understanding of TMDs (and TUDs) and their impact on the trade-wind region would further profit if the regional and seasonal foci was expanded beyond the BCO and the months January and February.

## 6 Summary and conclusion

In this paper we investigated the formation pathways of moist anomalies in the North Atlantic winter trades during the EUREC<sup>4</sup>A field campaign. We combined observational data with a detailed trajectory analysis based on ERA5 reanalysis data. Starting with a temporal overview of the atmospheric profiles above Barbados (Sect. 3), we found that the local conditions, as well as the large-scale circulation varied substantially during EUREC<sup>4</sup>A. For the most part, anomalies in the Eulerian framework were co-located with anomalies in the Lagrangian framework, which indicates that local conditions were strongly

influenced by the transport history of the air. To investigate the link between the air parcels' transport to Barbados and the formation of local moist anomalies, we conducted two detailed case studies of days from EUREC<sup>4</sup>A with moist anomalies in the lower (1000-650 hPa) and middle (650-300 hPa) troposphere, respectively. Both days were associated with exceptionally negative values of CRE.

The first case study (Sect. 4), on 22 January 2020, with a lower-tropospheric moist anomaly over Barbados is associated with a precipitating cloud band of a trailing cold front (a so-called Fish cloud following Stevens et al., 2020) that extended from about 30° N to Barbados and induced a locally strong cloud radiative cooling. The largest contribution to the moist anomaly came from air parcels following the pathway of an EDI (extratropical dry intrusion). The EDI and its interaction with the cold front were essential for the formation of the lower-tropospheric moist anomaly. Our analysis has shown that these air parcels experienced three moistening processes that plausibly only took place because of the presence of the EDI and the cold front: (1) the enhancement of ocean evaporation due to the strong vertical humidity gradient created by the EDI's subsidence and penetration into the (sub-)cloud layer, (2) the convergence of moisture and the formation of convective precipitation at the front, and (3) the evaporation of hydrometeors in the frontal region.

On a quasi-climatological time scale, EDIs are comparatively rare events in Barbados (~7 % occurrence frequency over the 11 Januaries and Februaries in 2010-2020). Very importantly, they can cause strongly contrasting conditions in Barbados. Either EDIs arrive in Barbados embedded in the cold sector associated with a dry lower troposphere and negligible precipitation, or they arrive together with the front leading to a humid lower troposphere, increased precipitation and an enhanced cloud radiative cooling. Indeed, eight EDIs contribute to the 33 days with the highest daily precipitation totals of the quasi-climatological period, but only three to the 33 moistest days. Thus other processes are responsible for most of the highest values of lower-tropospheric specific humidity in the quasi-climatological period.

The second case study (Sect. 5), on 14 February 2020, with a mid-tropospheric moist anomaly over Barbados is related to a horizontally extended mixed-phase shelf cloud that persisted over two days. This event was associated with the most negative CRE value during EUREC<sup>4</sup>A. As observed by radar, precipitation from the shelf cloud mostly evaporated/sublimated in the dry layer below, possibly initiating the formation of downdrafts due to evaporative cooling, thereby potentially triggering enhanced shallow convection from the surface. We hypothesise that this mechanism can feed moisture back into the mid-tropospheric cloud layer, thereby contributing to its substantial northward extension and persistence. The case study's moist anomaly was caused by air parcels that previously were detrained from cumulonimbi in the tropics. The pre-conditioning (the stable layer at the melting layer) for this TMD (tropical mid-level detrainment) came about due to a sharp vertical gradient in latent heating in tropical deep convective systems. With back-trajectories we showed that the case study's moist anomaly is directly linked to the convective activity over tropical South America.

In a quasi-climatological analysis, we identified days with tropical detrainment at mid-levels (TMDs) and at upper-levels (TUDs). Taken together, TMDs and TUDs have ~4 % occurrence frequency over the 11 Januaries and Februaries in 2010-2020. In 75 % of the cases, they led to an anomalously humid middle troposphere, whereof TMDs were associated with higher values of mid-tropospheric specific humidity than TUDs. Indeed, eight TMDs contribute to the 33 moistest days and five to the 33 days with the highest total column ice water content. Even though 14 and 15 February 2020 showed that mid-tropospheric clouds

trigger a strong short- and longwave radiative response, the daily mean CRE could not generally be linked to mid-tropospheric moist anomalies.

The detailed analysis of two case studies from EUREC<sup>4</sup>A and the accompanying quasi-climatological investigations have shown that extratropical and tropical dynamics periodically disturb the trade-wind region by inducing large-scale transport patterns that deviate from the usual low-level easterly and upper-level westerly flow regime. On the one hand, EDIs can cause the transport of air parcels from the extratropical upper troposphere to the lower troposphere near Barbados, where they either lead to anomalously dry or anomalously humid conditions associated with a locally enhanced cloud radiative cooling. On the other hand, deep convection in the ITCZ over South America can cause a stable layer near the 0° C-isotherm that promotes TMD and northwards transport, eventually leading to moist anomalies in the middle troposphere of Barbados, which, however, are not systematically linked to the CRE. Thus, the large-scale circulation and dynamical processes taking place remotely from the trade-wind region must be taken into account for the understanding of local humidity conditions. Moreover, our analysis highlights the great potential of combining the Eulerian and the Lagrangian perspectives based on reanalysis data with local observations.

*Data availability.* The ERA5 reanalyses are provided by the ECMWF and can be downloaded from the official website (<https://www.ecmwf.int/en/forecasts/datasets/reanalysis-datasets/era5>). The MODIS Terra satellite images of the Earth Observing System Data and Information System (EOSDIS) are available in the Worldview Snapshots application (<https://wvs.earthdata.nasa.gov>). The GOES-16 satellite images can be retrieved from the GIBBS imagery service (<https://www.ncdc.noaa.gov/gibbs/>). The measurements from the Vaisala WXT-520 meteorological ground station (<https://doi.org/10.25326/54>), the atmospheric soundings (<https://doi.org/10.25326/137>), and the Poldirad (<https://doi.org/10.25326/218>) can be obtained from the AERIS data repository. The cloud radar data is available on the BCO's official website (<https://barbados.mpimet.mpg.de/>).

*Author contributions.* LV performed most of the analysis, with help from FA, and wrote the paper. All authors added to the interpretation and presentation of the results.

*Competing interests.* The authors declare that they have no conflict of interest.

*Acknowledgements.* We thank Marina Dütsch (University of Vienna), Elisa Spreitzer (ETH Zürich), and Sara Müller (ETH Zürich) for scientific discussions on dry intrusions; Stefan Bühler (University of Hamburg) for an inspiring discussion about elevated moist layer on a EUREC<sup>4</sup>A campaign preparation workshop; Michael Sprenger (ETH Zürich) for the technical support; Sandrine Bony (Sorbonne University) and Bjorn Stevens (Max Planck Institute for Meteorology) (and other people involved) for the EUREC<sup>4</sup>A initiative; Claudia Stephan (Max Planck Institute for Meteorology) for coordinating the atmospheric sounding component of EUREC<sup>4</sup>A; the Max Planck Institute for

**Figure 1.** Illustrative schematics for (a) the definition of the vertical profiles above the BCO and (b) the calculation of the three-dimensional backward trajectories.

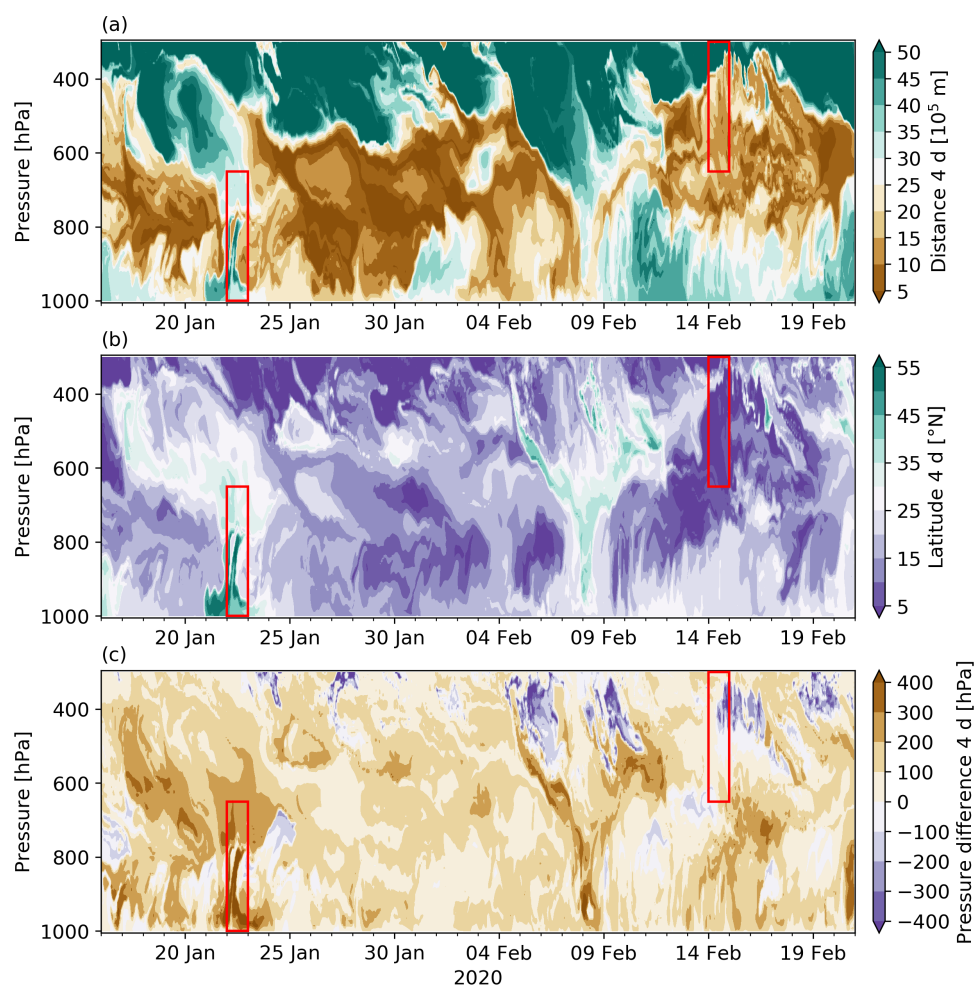

**Figure 2.** Time series of vertical profiles of the environmental conditions at the BCO during EUREC<sup>4</sup>A. Shown are (a) the anomaly in specific humidity relative to the level-specific campaign mean, liquid (blue contour), snow (black contour) and ice (brown contour) water content ( $10 \text{ mg kg}^{-1}$ ), (b) the zonal (color shading) and meridional wind ( $5, 10, 15 \text{ m s}^{-1}$ , dotted lines for negative values), and (c) vertical wind (color shading) and rain water content (black contour for  $1 \text{ mg kg}^{-1}$ ). A Gaussian filter was applied to all variables for better readability. The red boxes highlight the layers and periods of the two case studies.

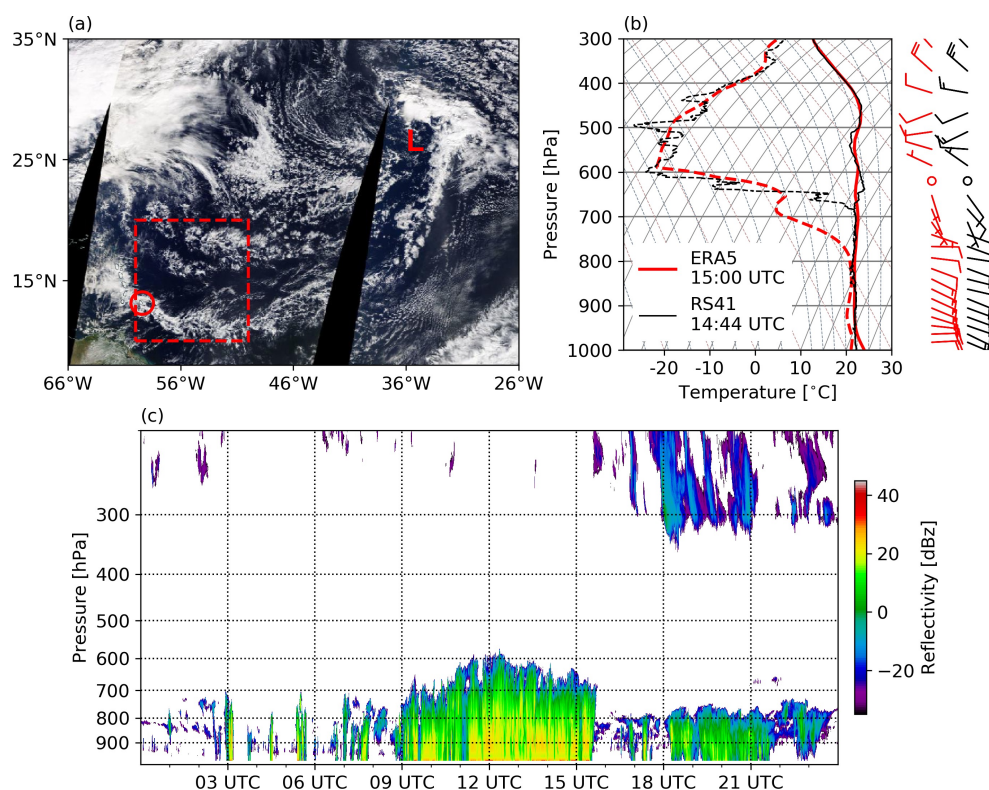

**Figure 3.** Time series of the environmental conditions at the BCO during EUREC<sup>4</sup>A. Shown are (a)  $IWV_{1000-650 \text{ hPa}}$  and  $IWV_{650-300 \text{ hPa}}$ , (b) hourly precipitation totals from ERA5 and the WXT-520 weather station (note the differently scaled y axes), and (c) CRE. The red shadings highlight the periods of the two case studies.

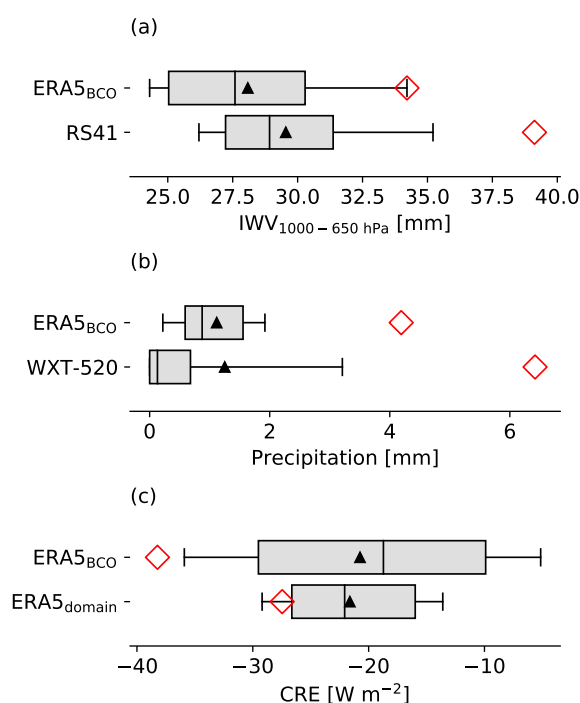

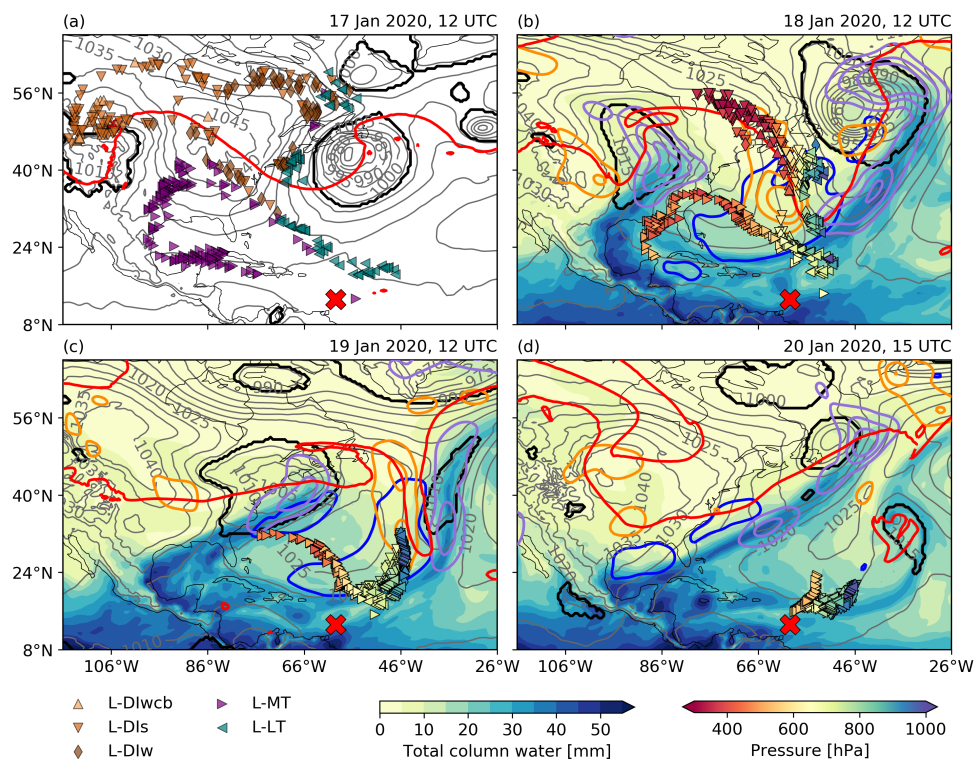

**Figure 4.** Time series of vertical profiles of the transport conditions at the BCO during EUREC<sup>4</sup>A. Shown are the air parcel's (a) great-circle distance from the arrival location travelled in the four days prior to arrival, (b) latitudinal position four days prior to arrival, and (c) pressure change along the trajectory during the four days prior to arrival (positive/negative values indicating descent/ascent towards the arrival location). A Gaussian filter was applied to all variables for better readability. Again, the red boxes highlight the layers and periods of the two case studies.

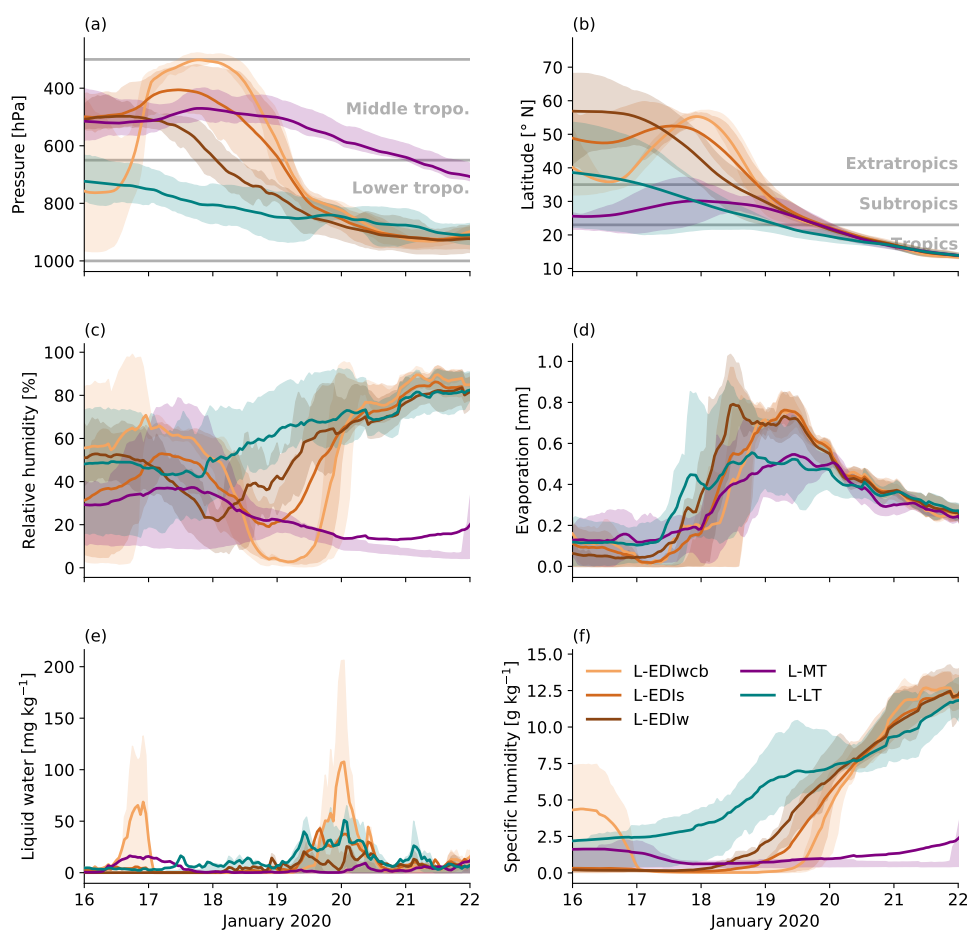

**Figure 5.** (a) MODIS Terra satellite image at about 14:30 UTC 22 January 2020 in the domain 8–35° N, 26–66° W, the location of Barbados (red circle), and the domain used for the domain-mean CRE calculation (10–20° N, 50–60° W; red box). (b) Vertical profiles of temperature (solid lines), dew point temperature (dashed lines), and wind (arrows) from ERA5 (red thick lines) and the atmospheric sounding (black thin lines) at about 15 UTC 22 January 2020. (c) Vertical profiles measured by the cloud radar (equivalent radar reflectivity of all hydrometeors) at the BCO on 22 January 2020.

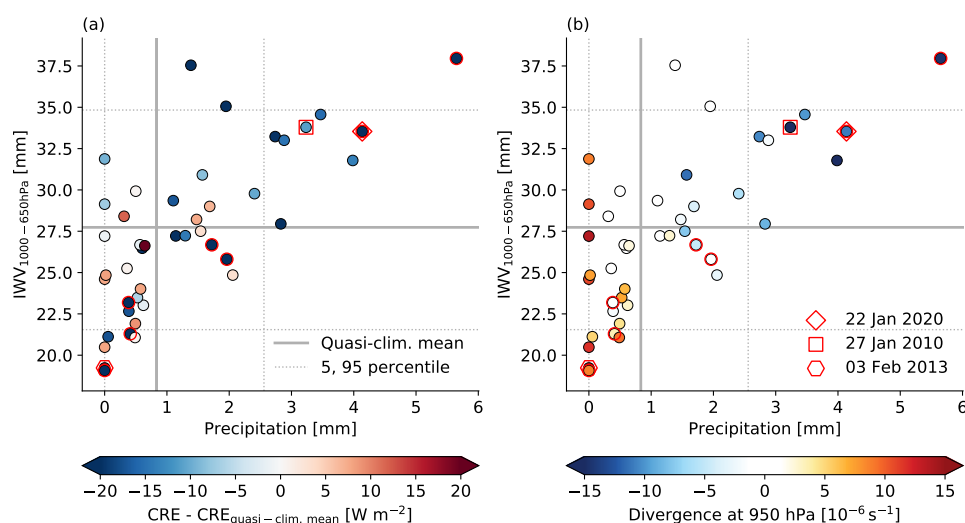

**Figure 6.** Boxplots of (a) daily mean  $I WV_{1000-650 \text{ hPa}}$  from ERA5 (ERA5<sub>BCO</sub>) and the atmospheric soundings (RS41) at the BCO, (b) daily precipitation totals from ERA5 and the weather station (WXT-520) at the BCO, and (c) daily mean CRE at the BCO and as area-weighted mean over the domain 10–20° N, 50–60° W (red box in Fig. 5a; ERA5<sub>domain</sub>). The boxplots (25, 75 percentiles as box; 10, 90 percentiles as whiskers; median as line in the box, mean as black triangle, outliers not shown) show values of 36 days (16 January to 20 February 2020). The values on 22 January 2020 are shown by red rhombi.

**Figure 7.** Synoptic situation over the North Atlantic and the position of backward trajectories from the BCO started in the layer 1000-650 hPa on 22 January 2020 (00-21 UTC, every 3 h) at (a) 12 UTC 17 January, (b) 12 UTC 18 January, (c) 12 UTC 19 January, and (d) 15 UTC 20 January 2020. Trajectory positions are shown as triangles coloured according to the (a) airstream or (b-d) pressure. Color shading shows total column water, and contours show sea level pressure (grey; 5 hPa intervals), cyclone masks (black), surface evaporation (blue; intervals of 0.5 mm h<sup>-1</sup>), upward and downward winds at 500 hPa (purple and orange, respectively; ±0.2, ±0.4, ±0.6 Pa s<sup>-1</sup>), and 2 pvu at 320 K (red). The red cross marks the location of Barbados. A Gaussian filter was applied to evaporation and vertical winds for better readability.

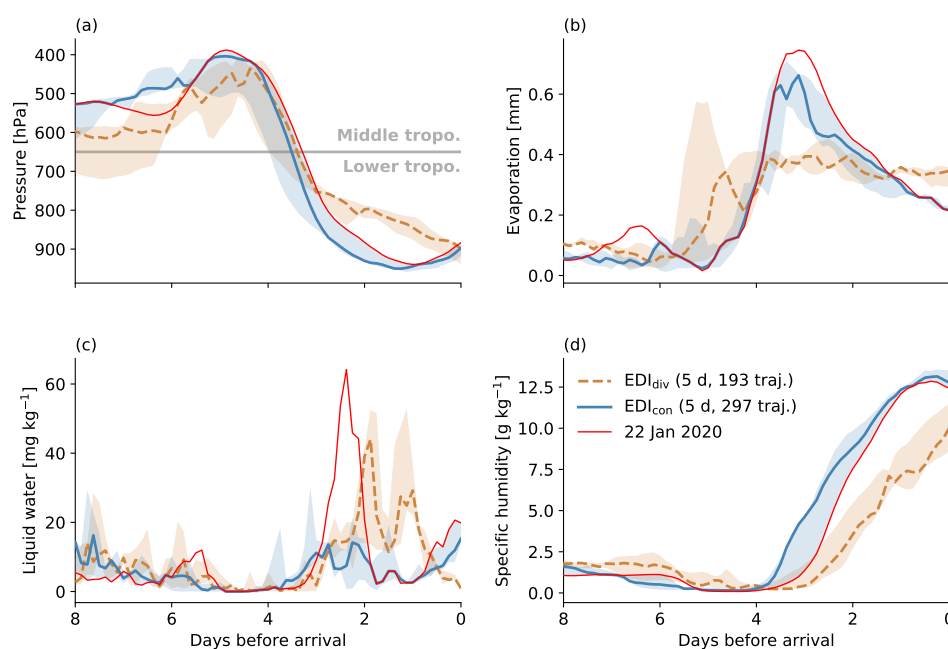

**Figure 8.** Time series along the five airstreams arriving at the BCO in the layer 1000–650 hPa on 22 January 2020. The variables shown are (a) pressure, (b) latitude, (c) relative humidity, (d) evaporation, (e) liquid water content, and (f) specific humidity. Thick lines show mean values and the shading the 25–75-percentile range. The number of trajectories assigned to each airstream is given in Table 1.

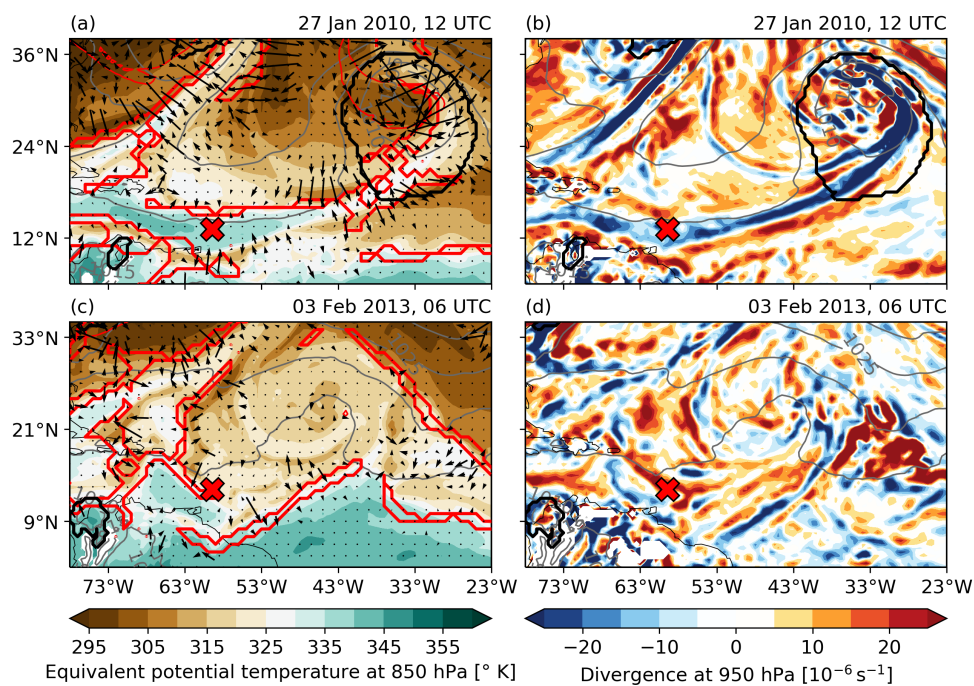

**Figure 9.** The relation between daily mean IWV<sub>1000-650 hPa</sub>, daily precipitation totals and (a) the anomaly in daily mean CRE relative to the quasi-climatological mean or (b) daily mean low-level divergence at the BCO is shown for the 44 EDI days. The quasi-climatological means are shown as gray continuous lines, and the 5 and 95 percentile as gray dashed line. The red geographical shapes indicate three specific dates, while the points with a red thick edge belong to the 33 days with the strongest cloud radiative cooling. Note that the daily mean values are based on three hourly data, thus the values are not directly comparable to Fig. 6.

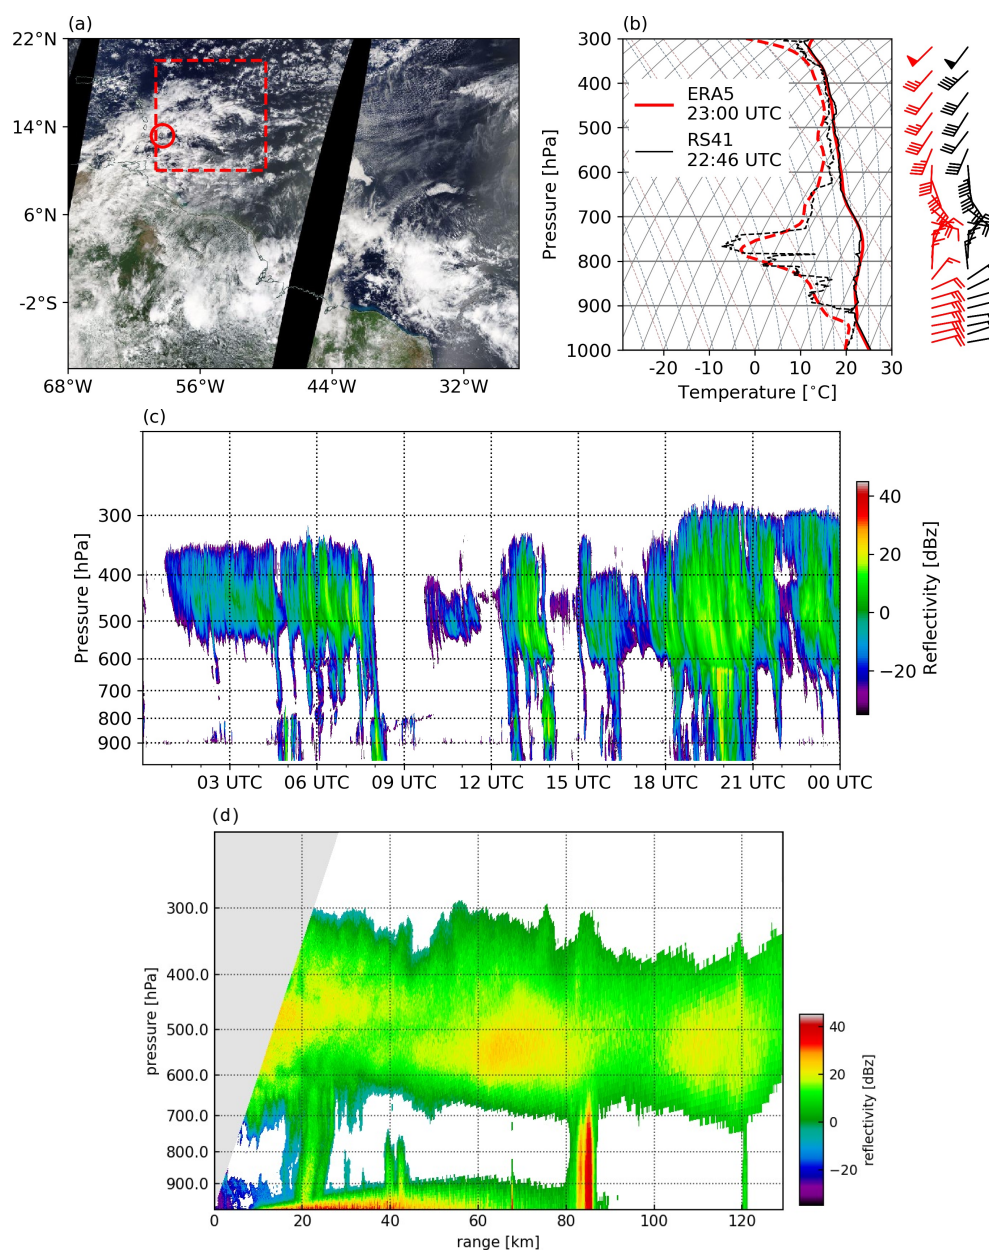

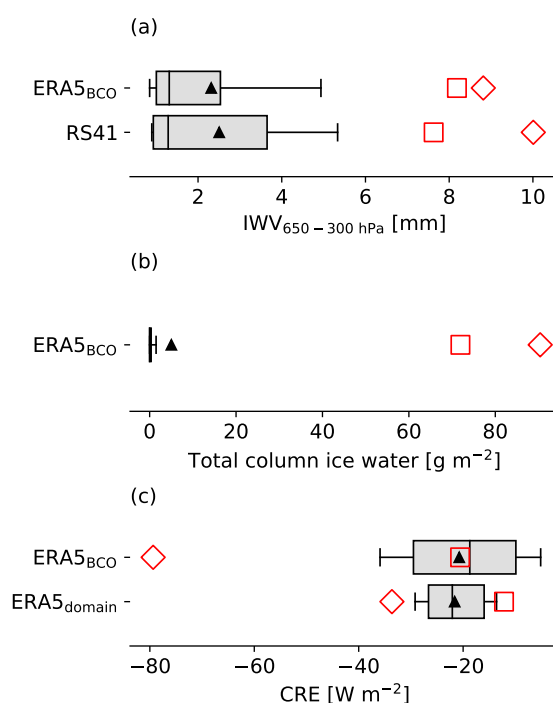

**Figure 10.** Time series along the EDI trajectories arriving at the BCO in the layer 1000-650 hPa during the quasi-climatological period. The variables shown are (a) pressure, (b) surface evaporation, (c) liquid water content, and (d) specific humidity. The thick lines show the mean and the shadings the 25-75-percentile range of the trajectories from the five EDI days with the strongest convergence/divergence (blue continuous/brown dashed lines). The mean of the EDI trajectories arriving on 22 January 2020 is shown as red thin line.

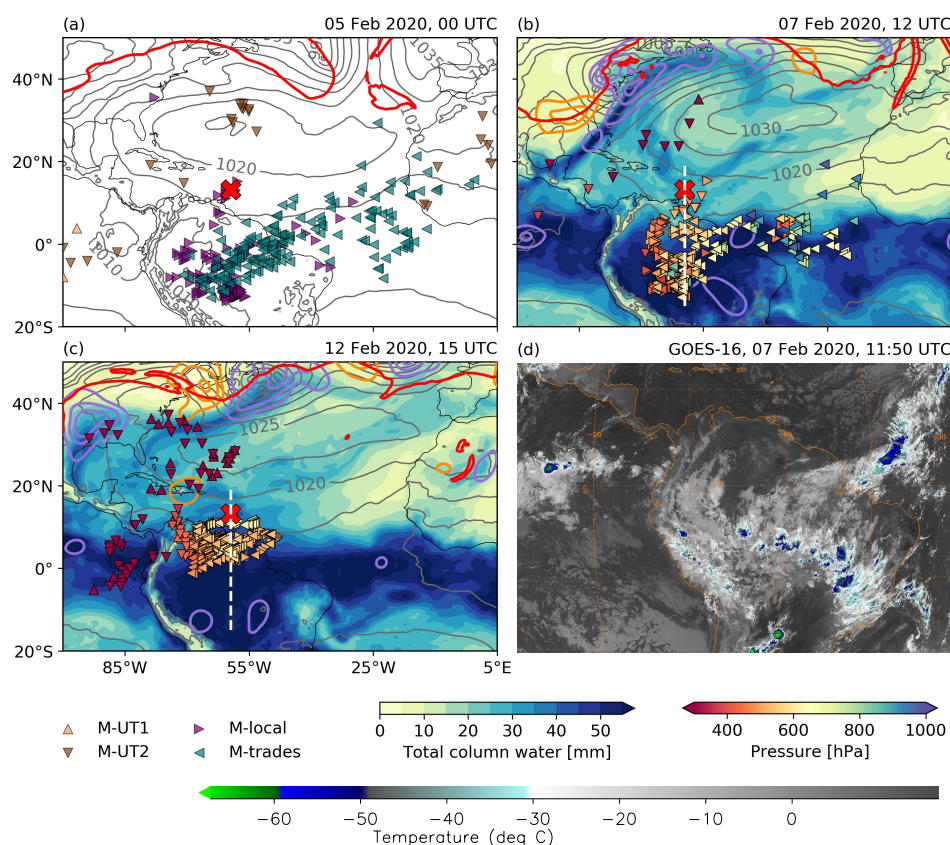

**Figure 11.** Synoptic situation over the North Atlantic on the EDI day with the strongest (a,b) low-level convergence (27 January 2010) and (c,d) low-level divergence (3 February 2013) in the quasi-climatological period. Shown are (a,c) equivalent potential temperature at 850 hPa (shading), ERA-Interim fronts (red thick contours), Q-vectors (calculated with the full horizontal wind at 850 hPa previously smoothed with a Gaussian filter), 2 pvu at 320 K (red thin contours); (b,d) horizontal divergence at 950 hPa (shading); sea level pressure (gray; 5 hPa intervals), cyclone masks (black), and the location of the BCO (red cross).

**Figure 12.** (a) MODIS Terra satellite image at about 14:30 UTC 14 February 2020 in the domain  $8^{\circ}\text{S}$ – $22^{\circ}\text{N}$ ,  $27$ – $68^{\circ}\text{W}$ , the location of Barbados (red circle), and the domain used for the domain-mean CRE calculation ( $10$ – $20^{\circ}\text{N}$ ,  $50$ – $60^{\circ}\text{W}$ ; red box). (b) Vertical profiles of temperature (solid lines), dew point temperature (dashed lines), and wind (arrows) from ERA5 (red thick lines) and the atmospheric sounding (black thin lines) at about 23 UTC 14 February 2020. (c) Vertical profiles measured by the cloud radar (equivalent radar reflectivity of all hydrometeors) at the BCO on 14 February 2020. (d) Vertical cross section measured by the Poldirad at 19:15 UTC on 14 February 2020 when the instrument was facing towards the BCO. Note, the shallow reflectivity layer between 10 and 90 km is sea clutter.

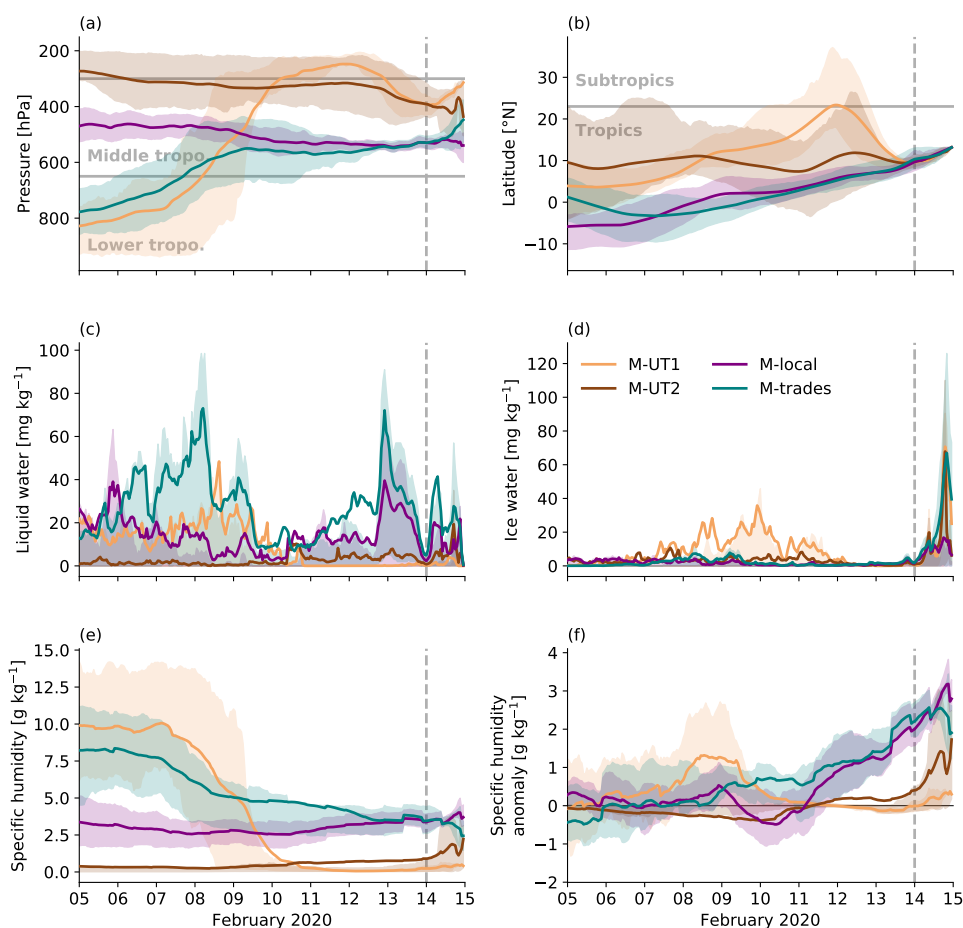

**Figure 13.** Boxplots of (a) daily mean IWV<sub>650-300 hPa</sub> from ERA5 (ERA5<sub>BCO</sub>) and the atmospheric soundings (RS41) at the BCO, (b) daily mean total column ice water at the BCO, and (c) daily mean CRE at the BCO and as area-weighted mean over the domain 10-20° N, 50-60° W (red box in Fig. 5a; ERA5<sub>domain</sub>). The boxplots (25, 75 percentiles as box; 10, 90 percentiles as whiskers; median as line in the box, mean as black triangle, outliers not shown) show values of 36 days (16 January to 20 February 2020). The values of 14/15 February 2020 are shown by red rhombi/squares.

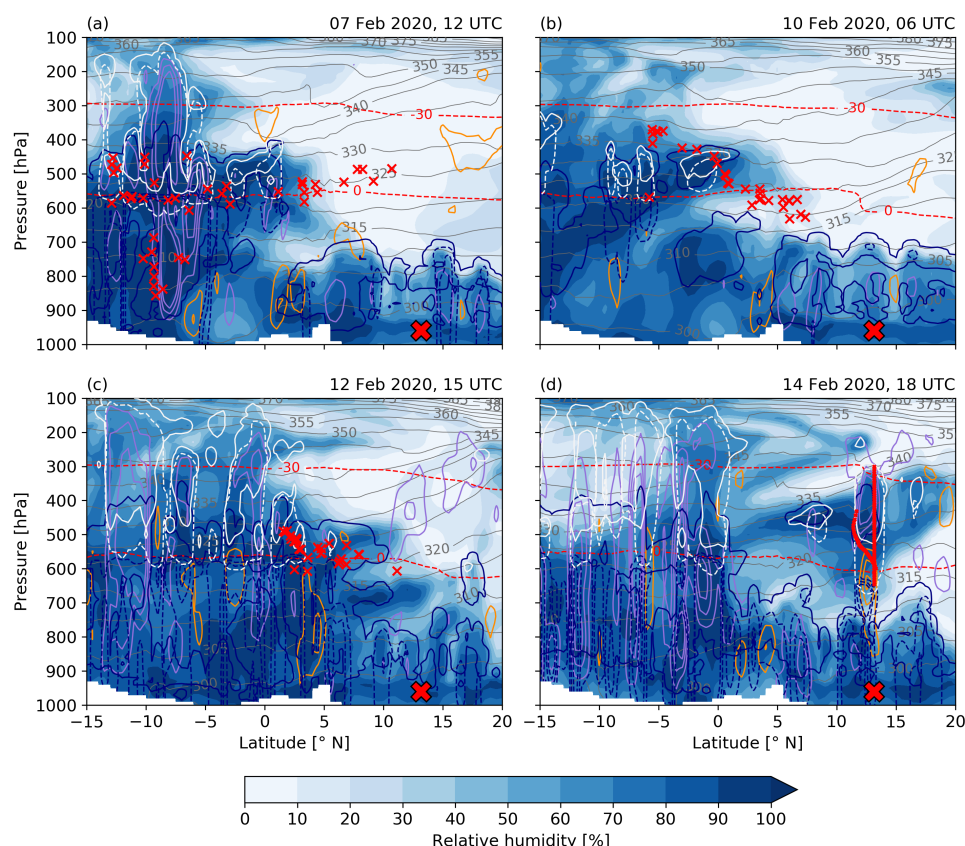

**Figure 14.** Synoptic situation over the North Atlantic and the position of backward trajectories from the BCO started in the layer 650–300 hPa on 14 February 2020 (00–21 UTC, every 3 h) at (a) 00 UTC 5 February, (b) 12 UTC 7 February, (c) 15 UTC 12 February 2020, and (d) cloud top temperature detected by the infrared channel (10.2 – 19.6  $\mu\text{m}$ ) of the GOES-16 satellite at 11:50 UTC 7 February 2020 (note the different projection). Trajectory positions are shown as triangles coloured according to the (a) airstream or (b,c) pressure. Color shading shows total column water, and contours show sea level pressure (grey; 5 hPa intervals), upward and downward winds at 500 hPa (purple and orange, respectively;  $\pm 0.2, \pm 0.4, \pm 0.6 \text{ Pa s}^{-1}$ ), and 2 pvu at 320 K (red). The red cross marks the location of Barbados and the white dashed line the location of the cross section shown in Fig. 16. A Gaussian filter was applied to the vertical winds for better readability.

**Figure 15.** Time series along the four airstreams arriving at the BCO in the layer 650–300 hPa on 14 February 2020. The variables shown are (a) pressure, (b) latitude, (c) liquid water content, (d) ice water content, (e) specific humidity, and (f) anomaly in specific humidity calculated relative to the level-specific campaign mean value at the location of the trajectory. Thick lines show mean values and the shading the 25–75-percentile range. The number of trajectories assigned to each airstream is given in Table 4. Note that from 00 UTC 14 February 2020 (gray dashed line) onward the number of trajectories in the airstreams continuously decreases as they reach the BCO.

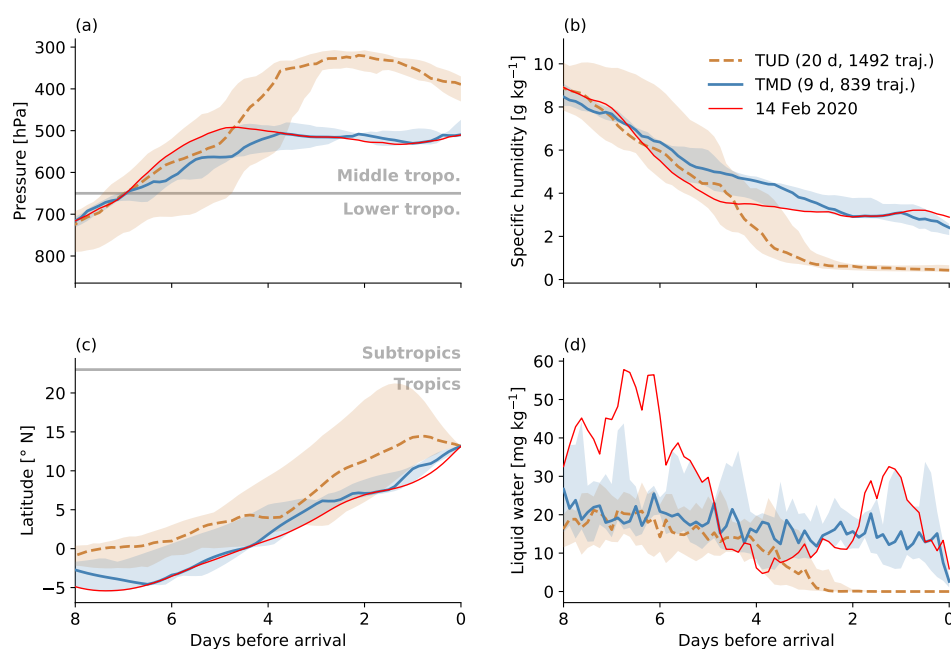

**Figure 16.** Cross section along  $-59.43^\circ$  W from  $15^\circ$  S to  $20^\circ$  N (white dashed line in Fig. 14) and the position of backward trajectories from the BCO started in the layer 650–300 hPa on 14 February (00–21 UTC, every 3 h) at (a) 12 UTC 7 February, (b) 6 UTC 10 February, (c) 15 UTC 12 February, and (d) 18 UTC 14 February 2020. Trajectory positions not more than  $\pm 1^\circ$  W away from the cross section are shown as red thin crosses, which are miniaturized in (d) for better readability. Color shading shows relative humidity, and contours show potential temperature (grey; 5 K intervals), 0 and  $-30^\circ$  C-isotherm (red dashed), upward and downward winds (purple and orange, respectively;  $\pm 0.2$ ,  $\pm 0.4$ ,  $\pm 0.6$  Pa s $^{-1}$ ), liquid (blue continuous), snow (white dashed), ice (white continuous; 10 mg kg $^{-1}$ ), and rain water (blue dashed; 1, 5, 10 mg kg $^{-1}$ ). The red thick cross marks the location of Barbados.

**Figure 17.** The relation between daily mean IWV<sub>650–300 hPa</sub>, the mean of the minimal pressure reached during the ten-day journey by the trajectories fulfilling the tropical detrainment criteria and (a) the anomaly in daily mean CRE relative to the quasi-climatological mean or (b) daily mean total column ice at the BCO is shown for the 29 TUD and TMD days. The quasi-climatological means are shown as gray continuous lines, and the 5 and 95 percentile as gray dashed line. The red geographical shapes indicate 14 and 15 February 2020. Note that the daily mean values are based on three hourly data, thus the values are not directly comparable to Fig. 13.

**Figure 18.** Time series along the trajectories undergoing tropical detrainment arriving at the BCO in the layer 650–300 hPa on the 20 TUD (brown dashed) and the 9 TMD days during the quasi-climatological period. The variables shown are (a) pressure, (b) specific humidity, (c) latitude, and (d) liquid water. Thick lines show the median value, and the shading the 25–75-percentile range. The mean of the tropical detrainment trajectories of 14 February 2020 is shown as red thin line.

**Table 1.** Size and humidity of the five airstreams arriving above the BCO in the layer 1000-650 hPa on 22 January 2020.

Airstream	Number of trajectories		Mean specific humidity per air parcel	Contribution to IWV <sub>1000-650 hPa</sub>
	Absolute count	Fraction of 1200		
L-EDIwcb	78	7 %	11.7 g kg <sup>-1</sup>	8 %
L-EDIs	311	26 %	12.5 g kg <sup>-1</sup>	34 %
L-EDIw	143	12 %	12.9 g kg <sup>-1</sup>	16 %
L-MT	423	35 %	4.5 g kg <sup>-1</sup>	16 %
L-LT	245	20 %	12.3 g kg <sup>-1</sup>	26 %

**Table 2.** The 44 EDI days from the quasi-climatological period shown in bold/cursive print if belonging to the five EDI days with the lowest/highest daily mean low-level divergence at the BCO. 2012 and 2015 are not shown because they have no EDI days.

Year	2010	2011	2013	2014	2016	2017	2018	2019	2020
Date	<b>27-28 Jan</b>	1 Jan 18 Jan 31 Jan 16 Feb <b>26 Feb</b> 28 Feb	14 Jan <i>17 Jan</i> 2,3,4 Feb	4 Jan <i>14-17 Jan</i> 27-28 Jan 15 Feb 18-19 Feb	<i>13-16 Jan</i>	1 Jan <b>13 Jan</b>	31 Jan-1 Feb <i>23-25 Feb</i> 28 Feb	1-2 Jan <b>27 Jan</b> 23-25 Feb	<b>22-24 Jan</b>
Count	2	6	5	10	4	2	6	6	3

**Table 3.** Pearson correlation coefficients matrix for the daily mean IWV<sub>1000-650 hPa</sub>, the daily precipitation totals, the daily mean CRE and the daily mean divergence at 950 hPa at the BCO for the 44 EDI (608 nonEDI) days of the quasi-climatological period.

	Precipitation [mm]	CRE [ $\text{W m}^{-2}$ ]	Divergence [ $10^{-6} \text{ s}^{-1}$ ]
IWV <sub>1000-650 hPa</sub> [mm]	0.71 (0.53)	-0.22 (-0.28)	-0.66 (-0.52)
Precipitation [mm]		-0.35 (-0.28)	-0.84 (-0.43)
CRE [ $\text{W m}^{-2}$ ]			0.37 (0.26)

**Table 4.** Size and humidity of the four airstreams arriving above the BCO in the layer 650-300 hPa on 14 February 2020.

Airstream	Number of trajectories		Mean specific humidity per air parcel	Contribution to IWV <sub>650-300 hPa</sub>
	Absolute count	Fraction of 1200		
M-UT1	84	7 %	0.4 g kg <sup>-1</sup>	1 %
M-UT2	205	17 %	0.8 g kg <sup>-1</sup>	6 %
M-local	316	26 %	3.1 g kg <sup>-1</sup>	33 %
M-trades	595	50 %	3 g kg <sup>-1</sup>	60 %

**Table 5.** The 20 TUD and 9 TMD (in bold print) days from the quasi-climatological period. 2012-2015 and 2018 are not shown because they have no TUD or TMD days.

Year	2010	2011	2016	2017	2019	2020
Date	12-13 Feb	29 Jan	17 Jan	14 Jan	12 Jan	<b>15-16 Jan</b>
	23, <b>24,25,26 Feb</b>	12-14,16,18 Feb	29 Jan	30 Jan	7 Feb	6 Feb
		24-25 Feb	14 Feb			<b>13-17 Feb</b>
Count	6	8	3	2	2	8

**Table 6.** Pearson correlation coefficients matrix for the daily mean  $IWV_{650-300 \text{ hPa}}$ , total column ice water, CRE at the BCO and the minimal pressure attained during the ten-day journey by the trajectories meeting the tropical detrainment criterion for the 29 TUD and TMD (and the remaining 623) days of the quasi-climatological period.

	Total column ice water [ $\text{g m}^{-2}$ ]	CRE [ $\text{W m}^{-2}$ ]	Minimal pressure [hPa]
$IWV_{650-300 \text{ hPa}}$ [mm]	0.61 (0.53)	-0.32 (-0.11)	0.78
Total column ice water [ $\text{g m}^{-2}$ ]		-0.39 (0)	0.51
CRE [ $\text{W m}^{-2}$ ]			-0.09
