Abstract. This study compares trends of the Hadley cell (HC) strength using different metrics applied to the ECMWF ERA5 and ERA-Interim reanalyses in the period 1979-2018. The HC strength is commonly evaluated by metrics derived from the mass-weighted zonal-mean stream function. Other metrics include the upper-tropospheric velocity potential, the vertical velocity in the mid-troposphere, and the water vapour transport in the lower troposphere. Seven known metrics of the HC strength are here complemented by a metric of the spatially-averaged HC strength, obtained by averaging the stream function in the latitude-pressure (φ - p) plane, and by the total energy of zonal-mean unbalanced circulation in the normal-mode function decomposition. It is shown that metrics, which rely on single-point values in the φ - p plane, produce unreliable 40-year trends of both the northern and southern HCs, especially in ERA-Interim; magnitudes and even the signs of the trends depend on the choice of the HC strength metric. The two new metrics alleviate the vertical and meridional inhomogeneities of the trends in the HC strength. In both reanalyses, there is a positive trend in the total energy of zonal-mean unbalanced circulation. The spatially-averaged HC strength metric also shows a positive trend in ERA5 in both hemispheres, while the trend in ERA-Interim is insignificant.

1 Introduction

The Hadley circulation is a thermally forced overturning circulation, consisting of two symmetrical cells, which span between the tropics and the subtropics. Each cell consists of the ascending branch in the deep tropics, which is associated with enhanced precipitation, poleward upper-tropospheric flow, and the descending motion in the subtropics that suppresses rainfall. The cell is completed by a frictional return flow in the lower troposphere. Therefore, potential changes of the Hadley cells (HCs), either to their strength or their meridional extent, will have a profound impact on the global hydrological cycle (Held and Soden, 2006; Burls and Fedorov, 2017) and the biosphere, particularly in the subtropics. For example, the subsidence region has already become drier, partly because of the enhanced descending motion, in line with the satellite observations of upper tropospheric humidity and total water vapor (Sohn and Park, 2010).

Several studies of the HC strength using reanalyses suggested strengthening of both the northern Hadley cell (NHC) and southern Hadley cell (SHC) in the recent decades. However, the reported magnitude and uncertainty of the trends differ (Tanaka

et al., 2004; Mitas and Clement, 2005; Stachnik and Schumacher, 2011; Nguyen et al., 2013; Chemke and Polvani, 2019). This is, alongside differences among reanalysis datasets (e.g. different resolutions and use of observations), study periods used and multidecadal variability (Masson-Delmotte et al., 2021; Zlotnik et al., 2021, in review), partly due to a variety of metrics that have been used to define the HC strength. For example, the strength of the overall Hadley circulation can be evaluated using the velocity potential in the upper troposphere, where the meridional divergent flow in the upper branch of the HC is strongest, which is associated with the maximal upward motions in the layer beneath (Tanaka et al., 2004). The Hadley circulation strength can also be defined by the maximum ascent at some predefined mid-tropospheric level (Wang, 2002). Both metrics describe the properties of the ascending branch of the Hadley circulation.

The majority of studies describe the HC by the mass-weighted zonal-mean stream function ψ in the latitude-pressure (φ - p) plane (Oort and Yienger, 1996). The ψ function is computed by the vertical integration of the zonal-mean meridional wind as

$$\psi(\varphi, p) = \frac{2\pi R \cos \varphi}{g} \int_0^p [v](\varphi, p') dp', \quad (1)$$

where $[v]$ is the zonal- and annual/seasonal-mean meridional wind, R is Earth's radius, g is gravity, φ is latitude, and p is pressure. Several metrics of the HC strength based on single-point values (maxima or minima) of $\psi(\varphi, p)$ have been used:

1. the maximum (minimum) values of ψ in the φ - p plane (e.g. Mitas and Clement, 2005; Stachnik and Schumacher, 2011; D'Agostino and Lionello, 2017);
2. the maximum (minimum) value of ψ at some selected pressure level, e.g. 500 hPa (e.g. Kang et al., 2013; Son et al., 2018; Chemke and Polvani, 2019; Mathew and Kumar, 2019; Menzel et al., 2019);
3. the vertical average of the maxima (minima) of ψ at different pressure levels in the troposphere (e.g. in the layer 200 hPa - 900 hPa, as in Nguyen et al. 2013).

In the past few years, several studies have compared different metrics of the tropical expansion (e.g. Solomon et al., 2016; Adam et al., 2018; Waugh et al., 2018). In contrast, the Hadley circulation strength has only been compared between different reanalyses and climate models (e.g. Stachnik and Schumacher, 2011; Chemke and Polvani, 2019). No study (to our knowledge) has yet compared the metrics of the HC strength in the same dataset. In this study, we perform such inter-comparison of HC metrics and we assess how the trends estimated by different metrics compare with each other in the ERA5 and ERA-Interim reanalyses. For example, we assess the sensitivity of the trends derived from metrics based on the latitude-pressure stream-function profile (1) to the choice of the pressure level. Motivated by uncertainties in the results based on the different metrics, we propose two alternative metrics of the HC strength: 1) a stream-function-based metric of spatially-averaged HC strength, and 2) an energy metric defined as the total energy of the zonally-averaged unbalanced circulation, to which the HC is the main contributor. The first is similar to the existing metrics and grasps the overall trends of each HC, whereas the second new metric is a more holistic approach that can be coupled to the global energy cycle but *a priori* does not distinguish between the NHC and SHC. Here the term 'unbalanced' denotes circulation that projects on the inertia-gravity (or non-Rossby) eigensolutions of the primitive equations (e.g. Kasahara and Qian, 2000).

The paper is organised as follows. Section 2 describes the data and methods including definition of various metrics. The metrics are compared in Section 3. Discussion and conclusions are given in Section 4.

2 Data and Methods

2.1 Reanalysis data

60 Two modern ECMWF reanalyses are analysed: ERA5 (Hersbach et al., 2020) and ERA-Interim (Dee et al., 2011). 40 years (1979-2018) of daily data at 00 UTC are used. Meridional wind (v), zonal wind (u), specific humidity (q), and vertical velocity (ω) data are provided on 37 pressure levels between 50°S and 50°N on latitude-longitude grid with 1° resolution for both reanalyses. Among these levels, 23 are between 1000 hPa and 200 hPa.

A new, energy-based metric is a product of a multivariate normal-mode function decomposition and it requires both wind
65 components and a pseudo-geopotential field that combines the hydrostatic geopotential and the mean sea-level pressure term (see section 2.2). Input data are in this case monthly mean fields on regular Gaussian grid F80 with 1.125° horizontal resolution and 137 hybrid model levels for ERA5, and 60 vertical levels for ERA-Interim.

ERA5 has a higher model resolution than ERA-Interim (0.3° compared with 1°, respectively). It also has an improved dynamical core and more detailed model physics (Hersbach et al., 2020). Advanced data assimilation procedures and new
70 observation operators allow ERA5 to assimilate five times more data than ERA-Interim. The radiative forcing depends on the long-term changes of the concentration of greenhouse gases and aerosols. The atmospheric model in ERA5 is forced by the state-of-the-art sea surface temperature (SST) and sea ice concentration (SIC) data, thus it is able to capture the low-frequency variability of the climate system better. Collectively, these upgrades result in a better agreement with the observations of tropospheric temperature, wind, humidity, and precipitation. Furthermore, the accuracy of the HC estimation is boosted
75 significantly by the reduced surface meridional wind and horizontal wind divergence bias over the oceans (Rivas and Stoffelen, 2019). Based on the above, we consider ERA5 a more reliable dataset.

2.2 Metrics of Hadley cell strength

The trends and their uncertainties are compared for several metrics of the HC strength:

1. maximum (minimum) of annual/seasonal-mean stream function between 40°S and 40°N, and between 200 hPa and 900
80 hPa, denoted ψ^{max} (ψ^{min}). Slightly different boundaries were employed by Mitas and Clement (2005); Stachnik and Schumacher (2011); D’Agostino and Lionello (2017); however, a reasonable choice of boundaries (e.g. excluding the lower part of the boundary layer and the stratosphere) does not affect the results;
2. maximum (minimum) of annual/seasonal-mean stream function at predefined pressure levels (e.g. 400 hPa, 500 hPa, etc.) within 40°S and 40°N, denoted $\psi^{max}(p)$ (or $\psi^{min}(p)$); as used in e.g. Kang et al. (2013); Chemke and Polvani
85 (2019); Menzel et al. (2019);

3. stream function value at the location of climatological (1979-2018) annual/seasonal-mean maximum (minimum) of the NHC (SHC) strength, $\psi(\varphi^{max}, p^{max})$, where $(\varphi^{max}, p^{max}) = \operatorname{argmax}_{(\varphi, p)}(\overline{\psi}_{1979-2018})$, and analogous for $\psi(\varphi^{min}, p^{min})$;
4. an average of maximum/minimum values of annual/seasonal-mean ψ over pressure levels between e.g. 200 hPa and 900 hPa, with a constant step size of 50 hPa, as in Nguyen et al. (2013):

$$90 \quad \langle \psi^{max} \rangle_p = \frac{1}{N} \sum_{i=1}^N (\psi(p_i))^{max}, \quad (2)$$

and analogous for $\langle \psi^{min} \rangle_p$;

5. maximum of the zonal-mean velocity potential $[\Phi]^{max}(p)$ at some predefined pressure level p , typically in the upper troposphere, e.g. at 200 hPa (Tanaka et al., 2004). The velocity potential is related to the wind divergence as $\nabla \cdot \mathbf{v} = \nabla^2 \Phi$;
6. minimum of the zonal-mean vertical velocity $[\omega]^{min}(p)$, i.e. maximum ascent, at some predefined pressure level p , typically in the mid-troposphere, e.g. at 500 hPa (Wang, 2002), or a minimum ω within the tropical troposphere ($[\omega]^{min}$).
7. spatially-averaged HC strength, which is obtained by spatially averaging the stream-function field in the latitude-pressure plane. For the NHC, it yields

$$\psi_{NHC} = \langle \psi(\varphi, p) \rangle, \quad \text{for } \psi(\varphi, p) > 0 \text{ and } (\varphi, p) \in [-15^\circ, 45^\circ] \times [100, 1000] \text{ hPa}, \quad (3)$$

where ψ is uniformly sampled latitudinally, and vertically with a 50 hPa step. Wide latitudinal boundaries ensure that the Hadley cell is fully contained in every season (as shown in Fig. 1). An analogous metric ψ_{SHC} is defined for the southern Hadley cell but with conditions $\psi < 0$ and meridional boundaries within $\varphi \in [-45^\circ, 15^\circ]$.

8. effective wind for the water vapour transport (Sohn and Park, 2010):

$$\mathbf{v}_E = \sum_{i=1}^N \frac{\text{PW}(i)}{\text{TPW}} \mathbf{v}_D(i). \quad (4)$$

The atmospheric column is divided into N layers in Eq. 4. In each layer i which spans from pressure level p_i to $p_{i-1} < p_i$, the amount of precipitable water is $\text{PW}(i) = \frac{1}{\rho_w g} \int_{p_i}^{p_{i-1}} q(p) dp$, where ρ_w is density of liquid water. The total precipitable water in the atmospheric column is $\text{TWP} = \int_{p_s}^0 q(p) dp$. Standard notations are used: g is acceleration of gravity, q is specific humidity, \mathbf{v}_D stands for divergent (irrotational) wind component, and p_s is surface pressure. The metric partially removes the influence of the change of total column water vapour (thermodynamic impact of warming climate) on the water vapour transport.

9. an energy-based metric I_M , which is defined as the total energy of the zonal-mean unbalanced circulation. Unbalanced circulation is derived using the normal-mode function decomposition and it corresponds to the circulation projecting onto the inertia-gravity eigensolutions (or IG modes) of the linearized primitive equations (Žagar et al., 2017). The projection of global geopotential and wind fields from reanalyses onto the normal-mode functions provides time series

115 of the complex expansion coefficients $\chi_{k,n,m}$ defined by the zonal wavenumber k , vertical mode index m and meridional mode index n for each IG and Rossby eigenmode. The IG modes of the mean zonal state ($k = 0$) are used to compute the total (kinetic plus available potential) energy as

$$I_M = \sum_m g D_m \sum_n |\chi_{0,n,m}^{\text{IG}}|^2, \quad (5)$$

120 where $|\cdot|$ denotes the absolute value. For every vertical eigenmode m , D_m denotes the associated eigenvalue known as the equivalent depth (e.g. Žagar et al., 2015, their Fig. 4), such that $D_1 > D_2 > \dots > D_M > 0$, where M is the maximal vertical wave number. Every combination (k, n, m) defines single component of the Hough harmonics expansion and the coupling between the geopotential height and winds. The amplitude of D_m defines the meridional scale of the modes that is associated with the radius of deformation on the equatorial β -plane, $a_e = g D_m / \beta$, where $\beta = 2\Omega/R$, and Ω is Earth's angular velocity. Higher modes with smaller equivalent depths correspond to stronger equatorial trapping; e.g., for $D_7 = 708$ m the trapping scale is roughly 17° . With all vertical and meridional modes included, the mean unbalanced circulation resides mainly within the tropics, and to a small extent near the major orographic features in the extratropics and in the polar winter stratosphere, as shown in Žagar et al. (2015, their Fig. 10). For details on the derivation and application of normal-mode functions the reader is referred to Žagar and J. Tribbia (2020). Two figures in Appendix illustrate the new metric. First, Fig. A2 shows the unbalanced circulation at 200 hPa level for four seasons illustrating that its seasonal march across the equator resembles the Hadley cell. Figure A3 confirms that the Hadley circulation is well represented by our new metric.

125
130

The described metrics have different properties. Metrics (1)-(4), (7) and (8) distinguish between the two Hadley cells, whereas metrics (5), (6) and (9) do not. Metrics (1) to (3) are sensitive to the vertical inhomogeneities in the strength of the Hadley cell by definition. Metric (8) describes only the return flow of the Hadley circulation in the lower troposphere. Metric (4) averages over the vertical but not the meridional inhomogeneity. Metrics (5) and (6) only describe the ascending branch of the Hadley circulation. New metric (7) alleviates the sensitivity to the spatial (meridional and vertical) inhomogeneities by spatial averaging. The same applies to the new metric (9), which is a global metric largely different from all other metrics, and applied here without any special tuning. Metrics (8) and (9) include nonlinear terms (Eqs. (4)-(5)), therefore the metrics are sensitive to the temporal averaging of the input data (e.g. hourly means, daily means, monthly means of daily means). In this study, monthly means are used for metric (8), consistent with Sohn and Park (2010), whereas metric (9) uses monthly means due to computational complexity.

135
140

In the following section, we explore the sensitivity of the trends to different metrics of the HC strength.

3 Sensitivity of the Hadley circulation trends to different metrics

3.1 Mean HC and its trend

Trends are evaluated from the time series of ψ for different single-point values $\psi(\varphi, p)$ as linear regression coefficients. The trends are considered significant if they pass the 95% threshold of the modified Mann-Kendall test using the trend-free pre-whitening method to eliminate the impact of serial autocorrelation (Yue and Wang, 2002; Hussain and Mahmud, 2019). Note that the trends presented in this study are only representative of the analysed 40-year period and that we do not evaluate the extent to which they represent a climate-change signal. A separate study (Zaplotnik et al., 2021, in review) addresses this question and its results suggest that a part of the recent 40-year trend in the HC strength may be due to the multi-decadal variability.

Fig. 1 shows climatological seasonal-mean stream function and its pointwise trends in the ERA5 reanalysis between 1979 and 2018. A significant enhancement of the winter cells can be observed: the northern Hadley cell (NHC; red contours) strengthens most in December-January-February (DJF), whereas the southern Hadley cell (SHC; blue contours) strengthens most in June-July-August (JJA). Both cells are strengthening between March and May (MAM). Note that trends in the seasonal-mean HC strength are spatially inhomogeneous across the cells, both meridionally and vertically. For example, in the winter NHC (DJF), the lower-tropospheric part of the descending branch is mostly strengthening, while the ascending branch of the cell in the deep tropics is weakening. From September to November (SON), the SHC exhibits significant strengthening in the ascending branch in the Inter-Tropical Convergence Zone, while its descending branch mostly shows insignificant strengthening/weakening and even significant weakening at the southern boundary of the cell. The inhomogeneities in trends are even more pronounced in the ERA-Interim reanalysis (Fig. A1); for example, vertical inhomogeneity in the SHC trend in MAM, JJA and SON is especially pronounced in the regions of the strongest ψ gradients. The presence of the inhomogeneities in the HC trends raises a question about the reliability of some of the trends derived from single-point metrics of the HC strength.

3.2 Comparison of the stream-function metrics

The sensitivity of the trends of the annual-mean and seasonal-mean HC strength to the stream-function metrics (1)-(4) and (7), described in Section 2.3, is shown in Fig. 2 for ERA5 and in Fig. A4 for ERA-Interim. In both reanalyses, large differences are observed between the trends of $\psi^{max}(p)$ at distinct pressure levels p (metric (2)). In ERA5, the multiyear trend of the annual-mean NHC (leftmost column in Fig. 2a) is $0.7 \cdot 10^8 \text{ kg s}^{-1} \text{ yr}^{-1}$ at 400 hPa and $2.2 \cdot 10^8 \text{ kg s}^{-1} \text{ yr}^{-1}$ at 800 hPa. For the SHC (Fig. 2b), $\psi^{min}(p)$ strengthens by $0.9 \cdot 10^8 \text{ kg s}^{-1} \text{ yr}^{-1}$ at 800 hPa and by $2.8 \cdot 10^8 \text{ kg s}^{-1} \text{ yr}^{-1}$ at 400 hPa. In ERA-Interim, the NHC exhibits even differences in the sign of trends (leftmost major column in Fig. A4a); a strengthening trend of $1.9 \cdot 10^8 \text{ kg s}^{-1} \text{ yr}^{-1}$ is present at 700 hPa and an insignificant weakening trend of $-0.3 \cdot 10^8 \text{ kg s}^{-1} \text{ yr}^{-1}$ at 400 hPa. The SHC has an insignificant trend of the annual-mean HC in the lower troposphere and a significant weakening of up to $-3 \cdot 10^8 \text{ kg s}^{-1} \text{ yr}^{-1}$ in the upper troposphere (leftmost major column in Fig. A4b), i.e. opposite to what ERA5 shows.

The differences between trends of seasonal-means at different pressure levels are even larger. For example, the winter NHC exhibits a large and significant strengthening in the lower troposphere (700-800 hPa) with trends around $4.5 \cdot 10^8 \text{ kg s}^{-1} \text{ yr}^{-1}$

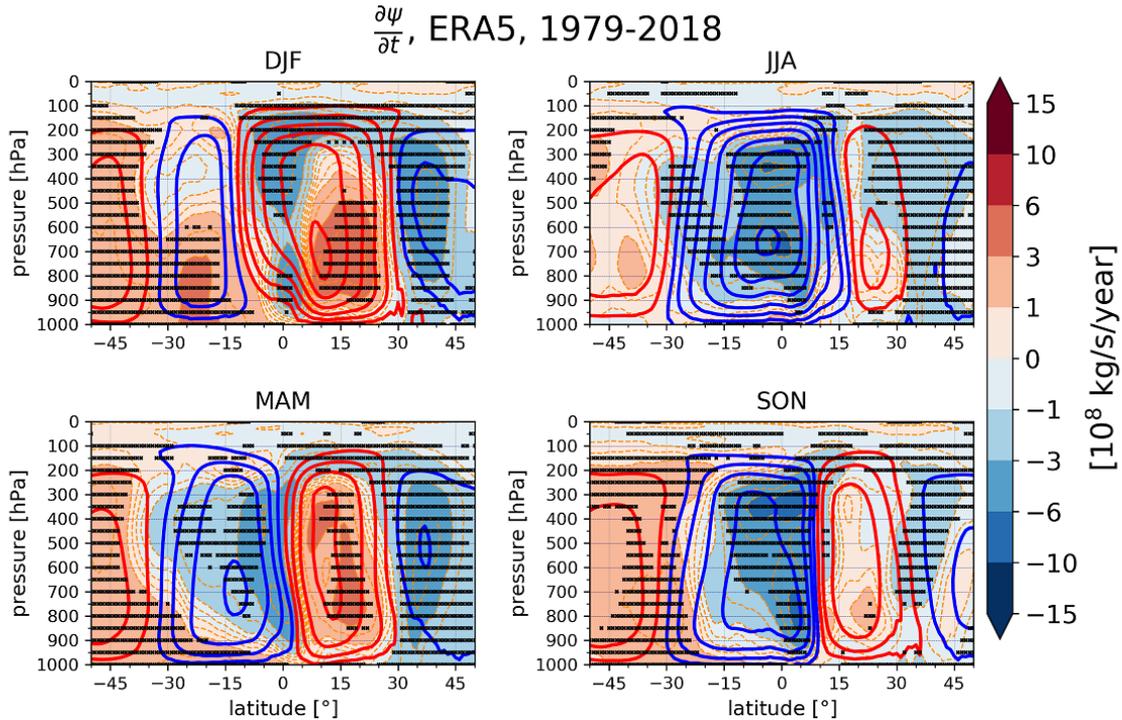

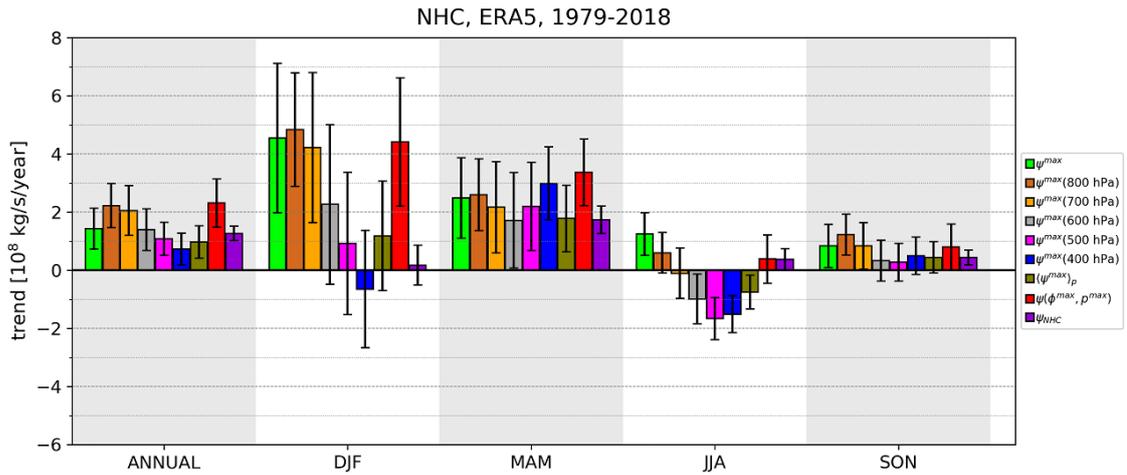

Figure 1. Seasonal-mean climatology of the Hadley Circulation (red and blue contours) and its trends (shading) in ERA5 reanalysis between 1979 - 2018. Red contours indicate positive climatological stream-function values, i.e. $(0.1, 0.3, 0.6, 1, 1.5, 2, 2.5) \cdot 10^{11} \text{ kg s}^{-1}$ and blue contours their negative equivalents, i.e. $(-0.1, -0.3, -0.6, -1, -1.5, -2, -2.5) \cdot 10^{11} \text{ kg s}^{-1}$. Crosses indicate the statistically significant trends at the 95% confidence level. Note that the overlapping of contours and shading of the same colour indicates strengthening of the cell, while overlapping of different colours indicates cell weakening.

175 in both ERA5 (Fig. 2a) and ERA-Interim (Fig. A4a); however the trends in the mid-troposphere (400-500 hPa) are mostly negative and/or insignificant. Different magnitudes of the trends at distinct pressure levels can partly be explained by the differences in the climatological-mean magnitude of the HC strength at different pressure levels. Normalization accounts for some of these differences; normalized results are discussed below at the end of Section 3.2 (see Figure 4).

The differences in the trends of seasonal-means at various pressure levels point towards the unreliability of the trend. Furthermore, magnitudes of the differences between metrics are of the same order as the uncertainties of the derived trends for individual metrics. Thus, by measuring the maximum HC strength at a selected pressure level, e.g. 500 hPa (as in metric (2)), the estimated trends are affected by the limitation of the metric.

Another notable feature of Figs. 2b and A4b is a significant difference between the trends of the annual-mean SHC strength in ERA5 and ERA-Interim reanalyses; the SHC is strengthening in ERA5 but weakening in ERA-Interim. In JJA and SON, the SHC is strengthening in both reanalyses by the majority of metrics, while in MAM, SHC is weakening in ERA-Interim

a)

b)

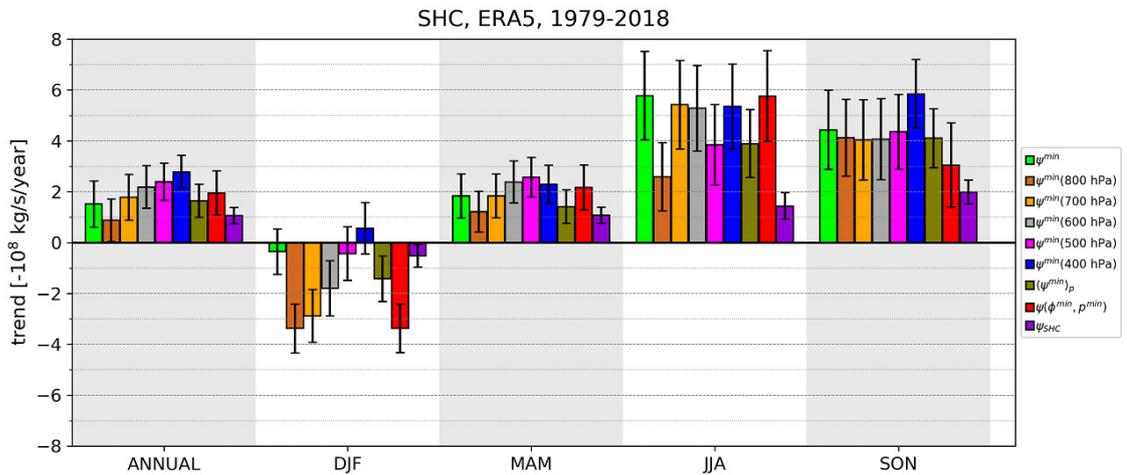

Figure 2. Trends of the NHC strength (a) and SHC strength (b) in ERA5 reanalysis between 1979-2018 for different stream-function metrics from Section 2.2. Annual-mean trends of the HC strength are shown in the first column, while seasonal-mean trends are shown in the other columns (as labeled). Different metrics of the HC strength are shown in the legend, e.g. in (a) for the NHC: ψ^{max} denotes annual/seasonal stream-function maximum (metric (1)), ψ^{max} at 400 hPa, 500 hPa, etc. denotes annual/seasonal stream-function maximum at respective pressure level (metric (2)), and $\psi(\phi^{max}, p^{max})$ denotes that the trends are measured at the point of the maximum stream function in a multiyear average of the NHC strength (metric (3)). $\langle \psi^{max} \rangle_p$ denotes vertically averaged ψ^{max} between 200 hPa and 900 hPa (metric (4), Eq. 2) and ψ_{NHC} denotes metric of spatially-averaged HC strength (metric (7), Eq. 3). Analogous notations are used for the stream-function minimum for the SHC in (b). Note that values in (b) are multiplied by (-1), thus positive values in both (a) and (b) indicate strengthening of the cell. Black error bars indicate standard error of the trend estimates.

and strengthening in ERA5. The reasons for such discrepancies are likely in the data assimilation modelling and treatment of observations, and are therefore beyond the scope of this study.

Metric (1) exhibits significant year-to-year variability in the levels of ψ^{max} , observed also by Mitas and Clement, 2005. ψ^{max} is switching between 350 hPa and 700 hPa levels in ERA5, and between 400 hPa and 650 hPa levels in ERA-Interim (Fig. A6, magenta and red lines). In contrast, the level of ψ^{min} remains roughly the same (700-750 hPa, blue and orange lines in Fig. A6) in both reanalyses throughout the studied period. Metric (1) also sometimes produces anomalous trends especially in the seasonal data, which do not align with any of the other metrics (e.g. in ERA5 NHC in JJA).

Metric (2) is sensitive to the vertical inhomogeneity in the trend of the HC strength (as seen from ψ at different levels in Figs. 2, A4). Metric (3) evaluates each Hadley cell in a spatially-fixed point throughout the observed period (1979-2018 in our study). Thus, we expect it to be susceptible to potential meridional shifts of the mean Hadley circulation (Grise and Davis, 2020) or vertical shifts due to vertically expanding tropical troposphere (Hu and Vallis, 2019). As a single-point metric, it also suffers from spatial inhomogeneity of the trend of the HC strength, similar to metrics (1) and (2).

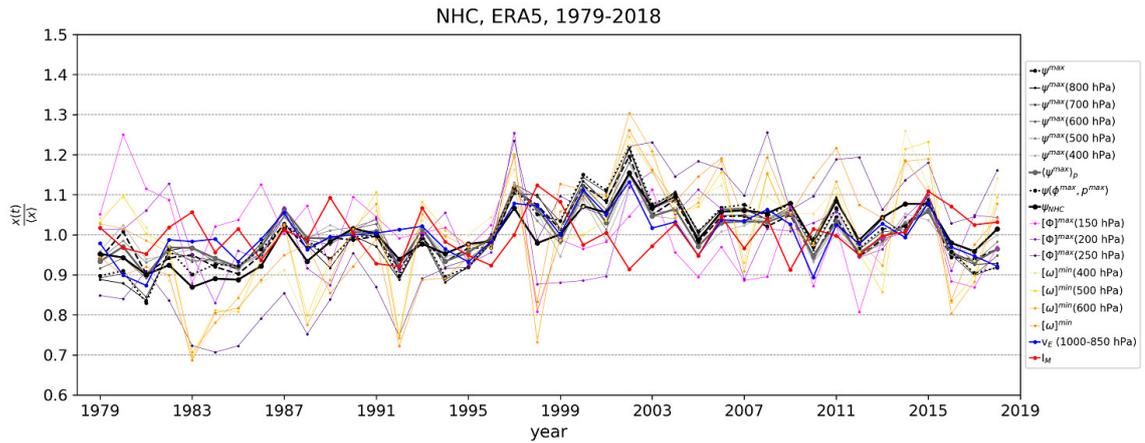

Vertically averaged maximum/minimum values of ψ as in metric (4) reduce the discrepancies associated with the varying pressure levels of stream-function maxima and minima. Metric (4) also grasps the differences in the trends of the HC strength and averages them. Furthermore, such a metric averages out the differences between the trends at different pressure levels, as well as the uncertainty due to the choice of the pressure level in metric (2). However, Fig. 1 also revealed significant trend inhomogeneities in the meridional direction, e.g. between the ascending and the descending branches of the Hadley circulation, which are addressed by the metric of spatially-averaged HC strength (i.e., by adding a meridional average).

The HC strength measured by (7) is on average weaker than in other ψ -based metrics as spatial averaging leads to smaller magnitude of ψ (not shown). Consequently, the trends are smaller (Figs. 2, A4, rightmost violet bar in each major column). When trends are spatially more homogeneous, metric (7) exhibits relatively smaller uncertainties than the other metrics (e.g. trends in seasonal means of the NHC in MAM, ERA5, Fig. 1 and Fig. 2a), and conversely for spatially less homogeneous trends (e.g. trends in seasonal-means of the NHC in JJA, ERA5, Fig. 1 and Fig. 2a). The spatially-averaged HC metric (7) thus provides an average over “extreme” local HC strength metrics (1-4), as well as an overall uncertainty. Figs. 2, A4 reflect the stronger year-to-year variability of seasonal means (compared with year-to-year variability of annual means), as well as larger discrepancies between ψ -metrics at different levels (as also seen from Figs. 1, A1). However from here on, we limit the analysis only to the trends (and variability) of the *annual-mean* Hadley circulation.

3.3 Comparison of stream-function metrics with other metrics

The time-series $X(t)$ of metrics with different units and different mean magnitudes can be compared after their normalisation by their respective climatological value of the 1979-2018 period (denoted \bar{X}). Results are shown in Fig. 3 for ERA5 reanalysis, including the normalized time-series of stream-function (ψ) metrics (1)-(4) and (7), velocity-potential (Φ) metrics (5), pressure-velocity (ω) metrics (6), water vapour transport metric, and metric (9) describing the total energy of the zonal-mean unbalanced circulation. Figure 4 and Table 1 present the trends of the normalized time-series, i.e. the relative trends $(\partial X/\partial t)/\bar{X}$ in

a)

b)

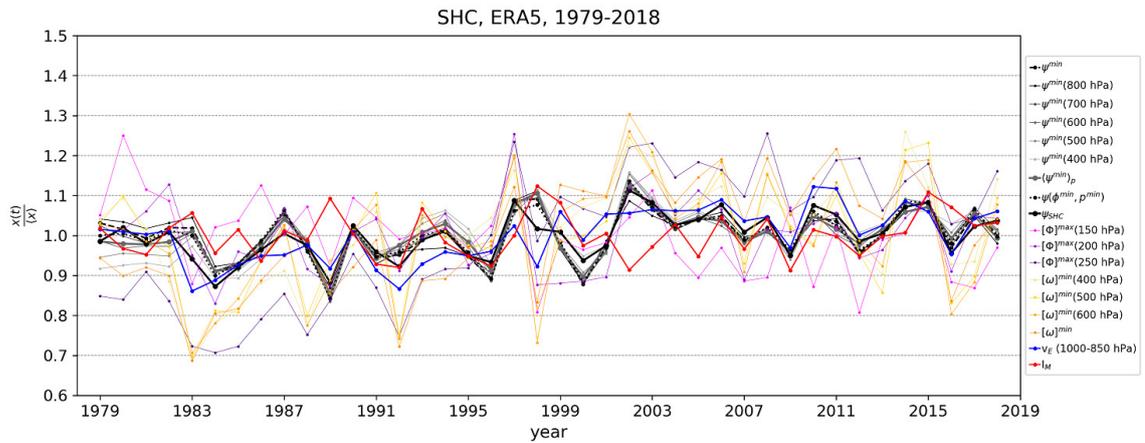

Figure 3. Time-series of the NHC strength (a) and the SHC strength (b) in ERA5 reanalysis between 1979–2018 for different metrics from Section 2.2. Time-series are normalized by their 1979–2018 climatological mean. Different stream-function metrics of the HC strength are shown in the legend (in grey colours), e.g. in (a) for the NHC: ψ^{max} denotes the annual/seasonal stream-function maximum (metric (1)); ψ^{max} at 800 hPa, 700 hPa, 600 hPa, etc. denotes the annual/seasonal stream-function maximum at respective pressure level (metric (2)); $\psi(\varphi^{max}, p^{max})$ denotes that the HC strength is measured at the point of the maximum stream function in a multiyear average of the NHC strength (metric (3)); $\langle \psi^{max} \rangle_p$ denotes the vertically averaged ψ^{max} between 200 hPa and 900 hPa (metric (4), Eq. 2); and ψ_{NHC} denotes the metric of the spatially-averaged HC strength (metric (7), Eq. 3). Analogous notations are used for the stream-function minimum for the SHC in (b). The following metrics do not distinguish between the two Hadley cells, but describe the Hadley circulation as a whole (their time-series are thus the same for NHC in (a) and SHC in (b)): $[\Phi]^{max}(p)$ denotes the maximum of the zonal-mean velocity potential at different pressure levels (metric (5), violet colours); $[\omega]^{min}(p)$ denotes the minimum of the zonal-mean vertical velocity (metric (6), orange colours); v_E denotes effective wind for the lower-tropospheric water vapour transport (metric (8), blue colour); and I_M denotes the normal-modes-based metric of the Hadley circulation (metric (9), red colour).

percentages per year, whereas Fig. 5 shows the correlations between the time-series of HC strength derived from different
220 metrics.

In general, the normalized metrics are well aligned in both HCs (Fig. 3, in grey colours), with a slightly larger spread over a few periods (e.g. 1979-1982 in both HCs). The time-series of ψ -metrics are better aligned for the SHC than the NHC, both in ERA5 and ERA-Interim (Fig. A5). They are also highly correlated (Fig. 5), as expected from Fig. 3. For example, the time-series derived from $\psi^{max}(p)$ (metric (2)) at nearby pressure levels (100 hPa apart) are highly correlated with correlation coefficient $r > 0.94$. Absolute ψ^{max} and ψ^{min} (metric (1)) correlate best with $\psi^{max}(p)$ and $\psi^{min}(p)$ at lower-to-mid-tropospheric
225 pressure levels (500-800 hPa). The result is in line with Fig. A6. Normalized metric (4) is highly correlated ($r > 0.9$) with $\psi^{max}(p)$ and $\psi^{min}(p)$ at various levels.

A widely utilized HC strength metric $\psi^{max}(500\text{hPa})$ (and similarly ψ^{max}) also highly correlates ($r = 0.85$) with the spatially-averaged HC strength metric (7), ψ_{NHC} . In the SHC, the stream-function minimum at 500 hPa yields a slightly
230 lower correlation ($r = 0.81$) with the spatially-averaged SHC strength metric, ψ_{SHC} . Even higher correlations ($r = 0.87$) with the spatially-averaged SHC strength are found for $\psi^{min}(p)$ at 700 hPa and ψ^{min} .

The above results suggest that the $\psi^{max}(p)$ metrics at pressure levels between 600 hPa and 500 hPa are most representative of the overall changes in the NHC, whereas $\psi^{min}(p)$ metrics around 700 hPa are most representative of the SHC. The other single levels should probably be avoided as the metrics of the overall HC strength.

235 The time-series of the other stream-function metrics, i.e. ψ^{max} or ψ^{min} , $\langle \psi^{max} \rangle_p$ or $\langle \psi^{min} \rangle_p$, $\psi(\varphi^{max}, p^{max})$ or $\psi(\varphi^{min}, p^{min})$ at the location of the climatological maximum or minimum also highly correlate ($r = 0.80$ to 0.89) with the spatially-averaged HC strength metric (7). This means that the newly proposed metric (7) is an adequate candidate for assessing the changes of the HC strength.

Despite the high correlations, the relative trends of ψ -metrics can differ significantly (Fig. 4; Tables 1, A1). ERA5 (Fig. 4a,c;
240 Table 1) shows mostly significant strengthening from 0.09 - 0.36% yr^{-1} for the NHC and 0.08 - 0.32% yr^{-1} for SHC. In the NHC, the widely used metric $\psi^{max}(500\text{hPa})$ shows strengthening of 0.14% yr^{-1} and is equal to the trend of $\langle \psi^{max} \rangle_p$, while ψ^{max} increases by 0.18% yr^{-1} . $\psi(\varphi^{max}, p^{max})$ and ψ_{NHC} show larger trends with strengthening of 0.29% yr^{-1} and 0.36% yr^{-1} , respectively. The two metrics that perform spatial averaging, $\langle \psi^{min} \rangle_p$ and ψ_{SHC} , suggest strengthening of the southern cell by 0.18% yr^{-1} and 0.23% yr^{-1} , respectively. The relative trends derived from the spatially-averaged HC strength metric
245 (7) show reduced uncertainty compared to the other stream-function-based single-point metrics, in line with the results of Section 3.2.

The time-series derived from ω -metrics have much higher temporal oscillations compared with ψ -metrics (Fig. 3), however the maxima and minima are fairly aligned with ψ -metrics, though with larger anomalies. This is captured also by their moderate correlations ($r = 0.3$ to 0.5 for the SHC and 0.4 to 0.65 for the NHC) (Fig. 5, A7). However, the spatially-averaged HC strength
250 (metric (7)), ψ_{NHC} and ψ_{SHC} , correlates better with the ω -metrics: $r = 0.70$ to 0.81 for the NHC and 0.65 to 0.72 for the SHC. The metric (7) also correlates better with the Φ -metrics than the other ψ -metrics, particularly with $[\Phi]^{max}$ at 200 hPa and 250 hPa. This further implies that the spatially-averaged HC strength (metric (7)) captures also the changes in the HC in regions of

Table 1. Annual-mean HC strength trends normalized by the climatological-mean values of the HC strength in ERA5 between 1979-2018. The trends derived from stream-function metrics (which distinguish between the NHC and the SHC), are separated by the horizontal black line from the trends, derived from other metrics (which describe the two cells together). The values in the parentheses denote standard error of the trend estimates.

NHC metric	trend (\pm unc.) [%/yr]	SHC metric	trend (\pm unc.) [%/yr]	HC metric	trend (\pm unc.) [%/yr]
ψ^{max}	0.177 (\pm 0.087)	ψ^{min}	0.136 (\pm 0.081)	$[\Phi]^{max}$ (150 hPa)	-0.375 (\pm 0.121)
ψ^{max} (800 hPa)	0.304 (\pm 0.104)	ψ^{min} (800 hPa)	0.082 (\pm 0.079)	$[\Phi]^{max}$ (200 hPa)	0.110 (\pm 0.126)
ψ^{max} (750 hPa)	0.298 (\pm 0.108)	ψ^{min} (750 hPa)	0.125 (\pm 0.080)	$[\Phi]^{max}$ (250 hPa)	1.136 (\pm 0.140)
ψ^{max} (700 hPa)	0.258 (\pm 0.108)	ψ^{min} (700 hPa)	0.160 (\pm 0.081)	$[\omega]^{min}$ (400 hPa)	0.519 (\pm 0.170)
ψ^{max} (650 hPa)	0.213 (\pm 0.102)	ψ^{min} (650 hPa)	0.192 (\pm 0.082)	$[\omega]^{min}$ (500 hPa)	0.349 (\pm 0.178)
ψ^{max} (600 hPa)	0.178 (\pm 0.091)	ψ^{min} (600 hPa)	0.214 (\pm 0.082)	$[\omega]^{min}$ (600 hPa)	0.412 (\pm 0.187)
ψ^{max} (550 hPa)	0.157 (\pm 0.080)	ψ^{min} (550 hPa)	0.233 (\pm 0.081)	$[\omega]^{min}$	0.738 (\pm 0.155)
ψ^{max} (500 hPa)	0.140 (\pm 0.073)	ψ^{min} (500 hPa)	0.257 (\pm 0.079)	I_M	0.072 (\pm 0.074)
ψ^{max} (450 hPa)	0.116 (\pm 0.070)	ψ^{min} (450 hPa)	0.280 (\pm 0.077)		
ψ^{max} (400 hPa)	0.094 (\pm 0.070)	ψ^{min} (400 hPa)	0.319 (\pm 0.075)		
$\psi(\varphi^{max}, p^{max})$	0.294 (\pm 0.106)	$\psi(\varphi^{min}, p^{min})$	0.177 (\pm 0.079)		
$\langle \psi^{max} \rangle_p$	0.136 (\pm 0.077)	$\langle \psi^{min} \rangle_p$	0.183 (\pm 0.073)		
ψ_{NHC}	0.358 (\pm 0.071)	ψ_{SHC}	0.232 (\pm 0.070)		
v_E^{NHC} (1000-850 hPa)	0.103 (\pm 0.078)	v_E^{SHC} (1000-850 hPa)	0.333 (\pm 0.076)		

ascending motion. The correlation of $[\Phi]^{max}$ at 150 hPa with other metrics is low and mostly insignificant, suggesting that the 150 hPa level might already be in the tropical tropopause.

255 The velocity-potential metrics $[\Phi]^{max}(p)$ show much larger magnitude of the trends compared with the other metrics. They are also very susceptible to the applied pressure level, a similar issue as for the ψ -metrics. Therefore, this metric is also likely susceptible to the potential future changes in the depth of the tropical troposphere. For example, $[\Phi]^{max}$ (250 hPa) in ERA5 shows a strengthening trend of 1.14% yr⁻¹, at 200 hPa roughly 0.11% yr⁻¹, whereas $[\Phi]^{max}$ at 150 hPa shows a weakening trend of -0.38% yr⁻¹ (Fig. 4a; Table 1), an outlier among the other metrics. The differences among trend magnitudes are even
260 larger in ERA-Interim (Fig. 4b; Table A1).

The trends derived from the ω -metrics align reasonably well with the trends derived from the ψ -metrics. In particular, $[\omega]^{min}$ at 500 hPa (dark grey bar in Fig. 4) shows good agreement with the spatially-averaged HC strength (metric (7)), but with more than doubled uncertainty due to larger variability of the ω -metrics, as revealed in Fig. 3. As for the other single-point metrics, the derived trends of the ω -based HC strength are strongly susceptible to the choice of the pressure level (this is again more
265 pronounced in the ERA-Interim).

The effective wind metric (8) aligns well with the stream-function metrics (Fig. 3), as reflected in their high correlations ($r = 0.68 - 0.86$) for the NHC and moderate correlations ($r = 0.43 - 0.52$) for the SHC. The exception is the high correlation

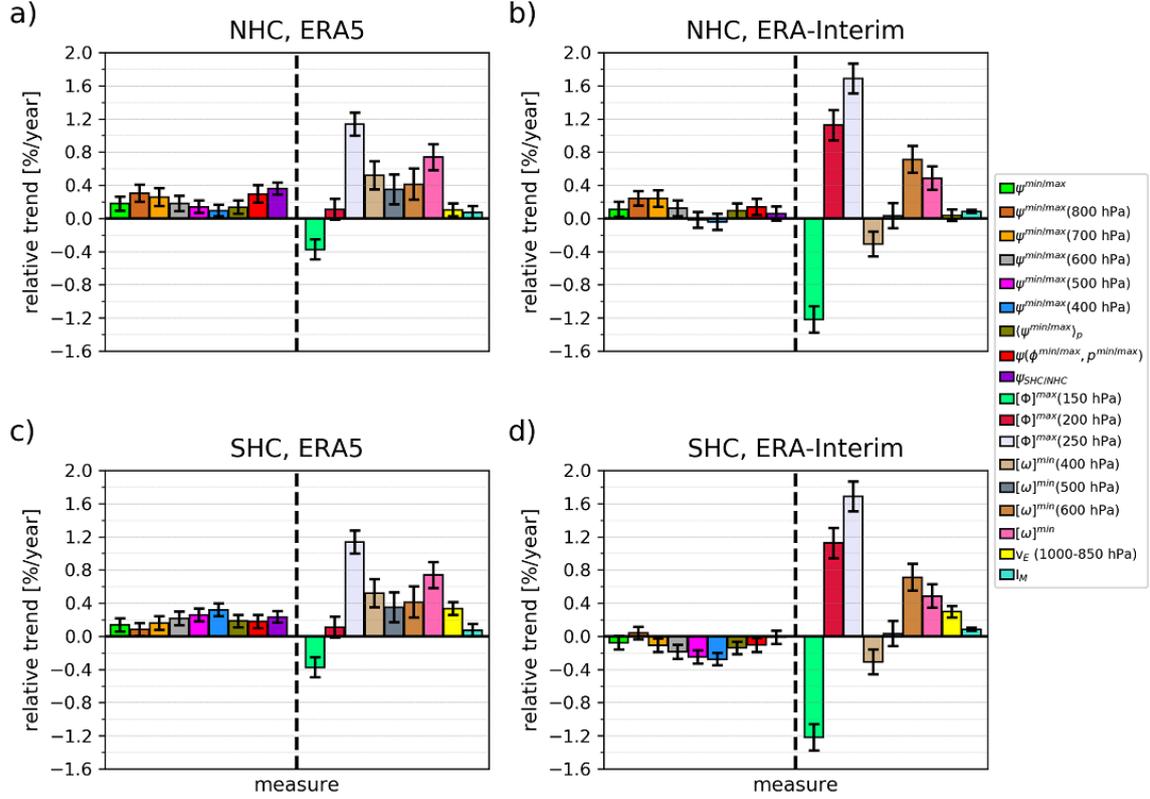

Figure 4. Annual-mean HC strength trends normalized by the climatological-mean values of the HC strength in the NH (a,b) and SH (c,d) in ERA5 (a,c) and ERA-Interim (b,d) reanalyses between 1979-2018 for different metrics of HC strength defined in Section 2.3. Different metrics of the HC strength are shown in the legend, e.g. for the NHC: ψ^{max} denotes the annual-mean stream-function maximum (metric (1)); ψ^{max} at 400 hPa, 500 hPa, etc. denotes the annual-mean stream-function maximum at respective pressure level (metric (2)); $\psi(\varphi^{max}, p^{max})$ denotes that the trends are measured at the point of the maximum stream function in a multiyear average of the NHC strength (metric (3)); $\langle \psi^{max}(t) \rangle_p$ denotes the vertically averaged $\psi^{max}(t)$ between 200 hPa and 900 hPa (Eq. 2) (metric (4)); and ψ_{NHC} denotes the metric of spatially-averaged HC strength (Eq. 3) (metric (7)). Analogous notations are used for the stream-function minimum for the SHC. The following metrics do not distinguish between the two Hadley cells, but describe the Hadley circulation as a whole (their results are the same for the NHC and the SHC, and are separated by the vertical black dashed line): $[\Phi]^{max}$ denotes the maximum of the zonal-mean velocity potential (metric (5)), $[\omega]^{min}$ denotes the minimum of the zonal-mean vertical velocity (metric (6)), v_E denotes effective wind for the lower-tropospheric water vapour transport (metric (8)) and I_M denotes the normal-modes-based metric of the Hadley circulation (metric (9)). Note that positive values in all panels indicate strengthening of the NHC and SHC. Black error bars indicate standard error of the trend estimates.

($r = 0.8$) of metric (8) with spatially-averaged metric ψ_{SHC} . The sign and the magnitude of the HC strength defined by metric (8) also aligns well with the stream-function-based metrics, except for SHC in ERA-Interim. On the other hand, for the NHC,

270 the effective wind metric (8) shows low (and insignificant) correlations with ω - and Φ -metrics describing the ascending branch of the HC, whereas it shows high correlations ($r \sim 0.7$) for the SHC (in both reanalyses). These results likely suggest that the northward water vapour transport to the deep tropics provides the bulk of the fuel for condensation, associated vertical motions and divergent outflow in the upper troposphere (described by the velocity potential).

The total energy of the zonal-mean unbalanced circulation I_M has strengthened in the 1979-2018 period in both reanalyses
275 with a rate of roughly $0.1\% \text{ yr}^{-1}$ (Fig. 4; Tables 1, A1). The uncertainty of the trend is smaller than in the other metrics. For ERA5, the sign of the derived trends is consistent with the other metrics. However, the I_M metric suggests strengthening of the HC also in ERA-Interim (Fig. 4b,d). This global trend in the HC strength is consistent with strengthening of the NHC derived from the other metrics in ERA-Interim, but is opposite to their trends of the SHC. Furthermore, the correlation of the energy metric with the other metrics is low and insignificant (Fig. 5), except for the $[\Phi]^{max}$ at 150 hPa. Insignificant correlations are
280 not surprising as this metric is largely different from all other metrics. First, it is the total energy metric; the kinetic energy is due to both components of the horizontal flow and there is a contribution to the energy also from extratropical troposphere and from the stratosphere. The part of I_M from the extra-tropics and the stratosphere is however arguably unimportant for the overall magnitude of the metric. Zagar et al. (2020) discussed the unbalanced circulation in ERA5 and ERA-Interim in relation to their observation processing and data assimilation setups, and showed that in spite of the differences, the two datasets agree
285 on the trends in the most energetic large-scale features of tropical circulation.

To quantify the role of the stratospheric circulation in the uncertainties of the trends for the I_M metric, we compared I_M in ERA-Interim focusing on levels up to about 93 hPa. It revealed a smaller, but still positive trend in ERA-Interim and a somewhat higher correlation with the other metrics (not shown). Given the importance of the mixed Rossby-gravity (MRG) waves in the Hadley circulation (Hoskins et al., 2020; Hoskins and Yang, 2021), we also tested an extension of the I_M , that includes also
290 energy of the MRG waves for all zonal wavenumbers in Eq. (5). In this case, the relative trend increased by a small margin, while the correlation with the other metrics remained insignificant (not shown). Furthermore, performing the summation (Eq. 5) for a subset of vertical modes (e.g. $m \geq 9$), thereby reducing the stratospheric and high-latitude contributions to the I_M , improved correlations with the other metrics, and also increased a trend, in a better alignment with the other metrics (not shown).

295 4 Conclusions and Outlook

In this study, we have analysed a number of metrics of the Hadley circulation strength including metrics based on the mass-weighted mean meridional stream-function, velocity potential, pressure velocity ω , water vapour transport, and the total energy of the zonal-mean unbalanced circulation. The metrics were applied to ERA5 and ERA-Interim reanalysis data between 1979 and 2018. While ERA5, a more recent and a more reliable reanalysis, is our main dataset, its comparison with ERA-Interim
300 provides confidence that the observed discrepancies between distinct metrics are not an isolated feature of ERA5 reanalysis. However, the comparison is not straightforward as the two reanalyses differ in their representations of the tropical circulation, including uncertainties that are difficult to quantify. These involve uncertainties in observations, differences in data assimilation

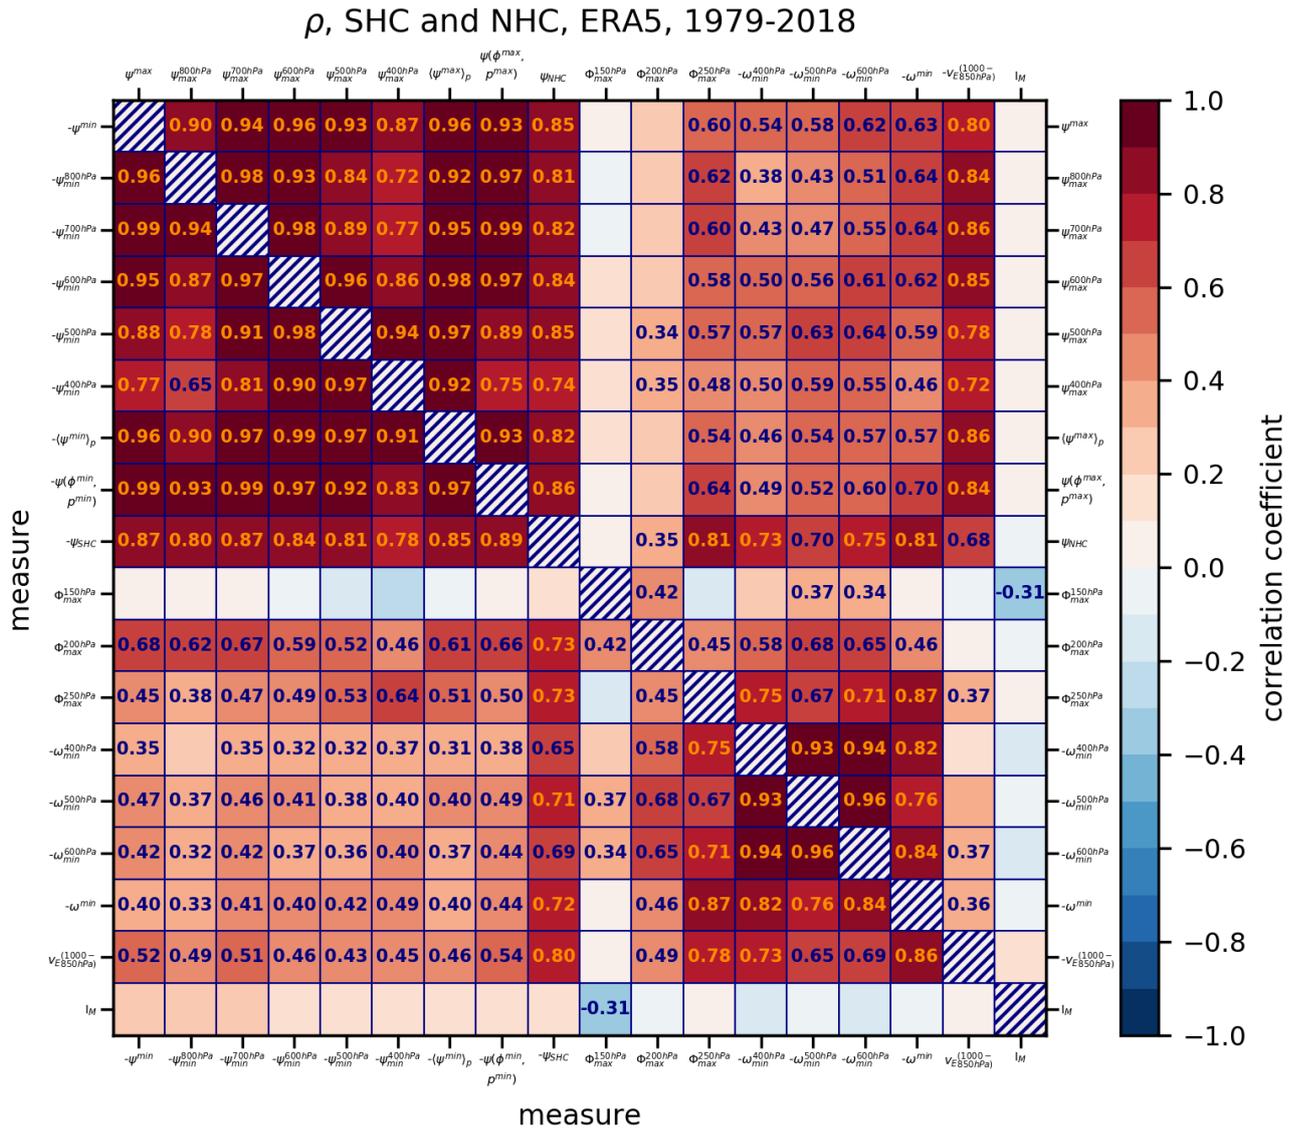

Figure 5. Correlations of time-series, derived from different metrics of the Hadley cell strength, described in Section 2.2, for 1979-2018 period in ERA5 reanalysis. The correlations for the northern Hadley cell are shown in the upper right part of the matrix, whereas the southern Hadley cell correlations are represented in the lower-left part. Time-series of $[\omega(p)]^{min}$ are multiplied by (-1) so that more positive values correspond to HC strengthening. Similarly, the time-series of the stream-function metrics ψ_{min} are also multiplied by (-1) so that more positive values correspond to HC strengthening. Only correlations exceeding 95% significance threshold are shown.

methodology, and general model differences. We have also proposed two new metrics that are based on averaging or integrating circulation properties to alleviate the character of some existing metrics. The first newly proposed metric describes the average strength of the NHC and SHC using spatially-averaged stream function and is therefore insensitive to spatial inhomogeneities. The other new metric quantifies the total energy of the unbalanced zonal-mean circulation.

By analysing the stream-function trends in the latitude-pressure plane, we showed that the trends are spatially inhomogeneous, both meridionally and vertically (Figs. 1,A1), particularly in ERA-Interim. Therefore, distinct stream function metrics of the HC strength resulted in significantly different and sometimes even opposing trends, decreasing our prospects to draw firm conclusions on the circulation changes. The same applies to other single-point metrics of the HC strength. The two new metrics of the HC strength are characterized by a smaller uncertainty of the derived trends compared to the current metrics, likely due to spatial averaging (average stream function) or the integration (total energy of zonal-mean unbalanced circulation).

Presented opposing trends suggest that the contribution of physical mechanisms that drive the Hadley cells and govern their strength (diabatic heating, friction, eddy heat and momentum fluxes, static stability, etc.) are likely to vary with the chosen HC strength metric (Chemke and Polvani, 2019; Zaplotnik et al., 2021, in review). For example, friction should affect the HC strength trends more if the metric $\psi^{max}(p)$ is taken at some lower-tropospheric pressure level, whereas its impact is likely reduced when $\psi^{max}(p)$ is evaluated at mid-to-upper tropospheric levels. Note that a detailed analysis of these effects is beyond the scope of this study and will be pursued in the future.

Because of the different mechanisms involved in the HC dynamics, the choice of the HC strength metric will ultimately depend on the application in a specific study. However, our results demonstrate that caution is needed when comparing HC trends from different studies using different metrics of the HC strength. In light of all the results, we therefore recommend using the spatially-averaged stream function as the metric of the HC strength (metric (7) from Section 2.2) whenever interested in the variability and trends of the overall HC strength. We also suggest an introduction of a unified metric of the HC strength (e.g. metric (7)) that will allow an easier comparison of the different studies on the topic of the *overall* HC strengthening/weakening. This would also allow a better estimation of the likelihood of the future changes in the global atmospheric circulation (e.g., Masson-Delmotte et al., 2021).

Code and data availability. Scripts are available upon request. The ERA-Interim and ERA5 reanalysis datasets are available from <http://www.ecmwf.int>. The data were obtained using Copernicus Climate Change Service information 2021. Data used to generate Figs. 2 to 5 and Figs. A3 to A6 are publicly available at <https://github.com/zaplotnik/Hadley-cell-strength> and published in Zenodo data repository: <https://zenodo.org/record/5135222#.YPzCMXUzb6c>.

Appendix A

MODES software (Žagar et al., 2015) is used to perform scale- and circulation-type-dependent decomposition of the 3D dynamical fields: the zonal wind u , meridional wind v and modified geopotential $h = P/g$ with $P = \Phi + RT_0 \ln p_s$. Here, Φ represents the geopotential, R is the gas constant, $T_0(p)$ is globally-averaged temperature on a certain pressure level. The input data vector $[u, v, h]^T$ is decomposed using separable series of M orthogonal vertical structure functions $G_m(p)$ and series of horizontal structure functions (Hough harmonics) $\mathbf{H}_n^k(\lambda, \varphi; m)$, which consist of $2K + 1$ zonal waves and R meridional waves:

$$\begin{bmatrix} u(\lambda, \phi, p) \\ v(\lambda, \phi, p) \\ h(\lambda, \phi, p) \end{bmatrix} = \sum_{m=1}^M G_m(p) \mathbf{S}_m \sum_{n=1}^R \sum_{k=-K}^K \chi_{knm} \underbrace{\Theta_n^k(\varphi; m)}_{\mathbf{H}_n^k(\lambda, \varphi; m)} e^{ik\lambda}, \quad (\text{A1})$$

where $\mathbf{S}_m = \text{diag}(\sqrt{gD_m}, \sqrt{gD_m}, D_m)$ is a diagonal matrix, g is gravitatonal acceleration. D_m is an equivalent depth of the vertical mode m and couples the vertical and horizontal structure functions. χ_{knm} are the spectral Hough coefficients. $\Theta_n^k(\varphi; m)$ is meridional vector function consisting of multivariately related components $[U_n^k, -iV_n^k, Z_n^k]^T(\varphi; m)$. For every vertical mode m , the system of horizontal structure equations applies

$$\begin{aligned} \frac{\partial u}{\partial t} - 2\Omega v \sin \varphi + \frac{g}{R \cos \varphi} \frac{\partial h}{\partial \lambda} &= 0 \\ \frac{\partial v}{\partial t} + 2\Omega u \sin \varphi + \frac{g}{R} \frac{\partial h}{\partial \varphi} &= 0 \\ \frac{\partial h}{\partial t} + D_m \nabla \cdot \mathbf{v} &= 0. \end{aligned} \quad (\text{A2})$$

The equations can be made dimensionless by taking $\tilde{u} = u'/\sqrt{gD_m}$, $\tilde{v} = v'/\sqrt{gD_m}$, $\tilde{h} = h'/D_m$ and $\tilde{t} = 2\Omega t$, so that

$$\frac{\partial}{\partial \tilde{t}} \mathbf{W}_m + \mathbf{L} \mathbf{W}_m = \mathbf{0}, \quad (\text{A3})$$

where $\mathbf{W}_m = [\tilde{u}, \tilde{v}, \tilde{h}]^T$ and \mathbf{L} is the linear differential matrix operator

$$\mathbf{L} = \begin{bmatrix} 0 & -\sin \varphi & \frac{\gamma}{\cos \varphi} \frac{\partial}{\partial \lambda} \\ \sin \varphi & 0 & \gamma \frac{\partial}{\partial \varphi} \\ \frac{\gamma}{\cos \varphi} \frac{\partial}{\partial \lambda} & \frac{\gamma}{\cos \varphi} \frac{\partial}{\partial \varphi} (\cos \varphi(\cdot)) & 0 \end{bmatrix}. \quad (\text{A4})$$

γ is a dimensionless parameter defined as the ratio of shallow-water gravity wave speed and twice the rotation speed of Earth, $\gamma = \sqrt{gD_m}/(2R\Omega)$. The third equation in system (A2) now becomes

$$\frac{\partial \tilde{h}_m}{\partial \tilde{t}} + \frac{\sqrt{gD_m}}{2\Omega} (\nabla \cdot \tilde{\mathbf{v}}_m) = 0, \quad (\text{A5})$$

The solution ansatz can be expressed by assuming separability of time-dependent and space-dependent solutions, i.e.

$$\mathbf{W}_m(\lambda, \phi, \tilde{t}) = \mathbf{H}_n^k(\lambda, \phi; m) e^{-i\tilde{\sigma}_{knm}\tilde{t}}, \quad (\text{A6})$$

where $\tilde{\sigma}_{knm}$ is dimensionless frequency, and $\mathbf{H}_n^k(\lambda, \varphi; m)$ are the associated horizontal structure functions, which are used in the expansion (A1).
