### Abstract.

The number of sudden stratospheric warmings (SSWs) per year is affected by the phase of the El Niño–Southern Oscillation (ENSO), yet there are discrepancies between the observed and modeled relationship. We investigate how systematic model  
10 biases may affect the ENSO-SSW connection. A two-step bias-correction process is applied to the troposphere, stratosphere or full atmosphere of an atmospheric general circulation model. ENSO type sensitivity experiments are then performed to reveal the impact of differing climatologies on the ENSO–SSW teleconnection.

The number of SSWs per year is overestimated in the control run, and this statistic is improved when stratospheric biases are reduced. The seasonal cycle of SSWs is also improved by the bias corrections. The composite SSW responses in the  
15 stratospheric zonal wind, geopotential height and surface response are well represented in both the control and bias corrected runs. The model response of SSWs to ENSO phase is more linear than in observations, in line with previous modeling studies, and this is not changed by the reduced biases. However, the trend of more wave-1 events during El Niño years than La Niña years is improved in the bias corrected runs.

## 20 1 Introduction

The El Niño-Southern Oscillation (ENSO) can impact the northern hemisphere wintertime stratospheric variability, and the prevalence of sudden stratospheric warmings (SSWs). Understanding the ENSO-SSW link can help interpreting seasonal model predictions and improve seasonal forecasts. The increased convection in the tropical east Pacific during an El Niño event triggers a Rossby wave train that strengthens and deepens the Aleutian low (Bell et al. 2009; Cagnazzo and Manzini  
25 2009). This leads to constructive linear interference of the planetary waves and an increased wave flux into the stratosphere, and hence, a weakened stratospheric polar vortex. During El Niño years the polar vortex is, on average, weaker than in neutral years, and El Niño is also associated with an increase in the number of SSWs (Domeisen et al., 2019).

Although La Niña is the opposite phase to El Niño, the negative SST anomalies tend to be weaker, more westward, and have a different time evolution (Hoerling et al., 1997, Larkin & Harrison, 2002, Frauen et al., 2014). The decrease in convection  
30 in the tropical east Pacific associated with La Niña still leads to a shallower Aleutian low, decreased wave flux and a stronger polar vortex (Iza et al., 2016, Jiménez-Esteve, B., & Domeisen, D. I. V., 2019, Domeisen et al., 2019). The anomalous La Niña response is weaker than El Niño due in part to the weaker response of the tropical convection and Rossby wave forcing (Trascasa-Castro et al., 2019). The changes to the vertical wave activity flux seem a valid dynamical argument as to why El Niño might lead to more SSWs and La Niña lead to less SSWs, however, the observational record is not so clear. There is a  
35 higher chance of an SSW during El Niño years, but there is also an increase in SSW frequency associated with La Niña years (Butler et al., 2014). However, there may be sampling errors due to the relatively short observational record (Domeisen et al., 2019), and the La Niña-SSW relationship is sensitive to the SSW definition (Song & Son 2018). Modeling studies show the increased likelihood of an SSW during an El Niño, and show a decrease likelihood of SSWs during La Niña years (Polvani et al., 2017, Song & Son, 2018). It is unclear if the discrepancy between models and observations is due to the low  
40 number of observed ENSO and SSW events in observations, or non-linearities in the ENSO teleconnections which the models are unable to simulate (Domeisen et al., 2019).

The role of mean state model biases has been investigated for some aspects of the ENSO-SSW teleconnection. Biases in the tropical Pacific SSTs can lead to different ENSO dynamics (Bayr et al., 2018), and affect the position of the North Pacific sea level pressure response (Bayr et al., 2019). Mean state biases in the extratropical circulation can affect the propagation of  
45 Rossby waves (Li et al., 2020), and their impact on North Pacific SSTs (Dawson, et al., 2011). The impact of climatological biases on the mean ENSO-to-northern hemisphere teleconnection was discussed in Tyrrell and Karpechko (2021), using output from the same modeling experiments as in this paper (see Section 2). It was found that mean state of the Aleutian low changed the response of the polar vortex to an El Niño forcing by modulating the upward wave flux to the stratosphere. Biases in the strength of the polar vortex did not impact its anomalous response to ENSO, and the NAO response was not  
50 impacted by biases.

In this paper we investigate how the climatological biases affect the relationship between ENSO and northern hemisphere SSWs. We use a bias correction technique to reduce atmospheric biases at specific levels to create different climates, within which we can run ENSO-like SST perturbation experiments. The bias correction technique and data are described in Section 2, in Section 3 we present the bias reductions and mean ENSO response (3.1), the statistics of SSWs (3.2), downward  
55 propagation and the surface response (3.3), and the heatflux response (3.4). A discussion and conclusions are presented in Section 4.

## 2 Data and Methods

### 2.1 Bias corrections

We used the ECHAM6 atmospheric model (Stevens et al., 2010), with a horizontal truncation of T63 and 95 levels in  
60 vertical with a model top at 0.02 hPa. It was run in bias-corrected and biased modes and with SST perturbation experiments. The bias correction process follows Kharin and Scinocca (2012), and has been used to study the effects of model biases on the Eurasian snow extent-polar vortex connection (Tyrrell et al., 2020), Quasi-Biennial Oscillation teleconnections (Karpechko et al., 2021) and the ENSO-northern hemisphere winter teleconnections (Tyrrell and Karpechko (2021)) and involves two steps: first, the dynamic variables of the model (divergence, vorticity, temperature, and log of surface pressure)  
65 are nudged towards ERA-Interim reanalysis. During this step the nudging tendencies are recorded every 6 hours. Forty years of nudging tendencies are then composited and smoothed to create an annual climatology of the nudging tendencies. This climatology represents the inherent biases in the model. In the second step, the nudging tendency climatology is added to the model as an additional tendency at each timestep, in order to correct the biases in the model's climatology. For the second step it was found that the biggest reduction in biases occurred when only the divergence and temperature were corrected. The  
70 dynamic variables of ECHAM6 are solved using a spectral decomposition of the globe, which allows for nudging and bias correcting on specific wavenumbers. Wavenumbers below  $n = 21$  were nudged and corrected, which means features below about 1000km were not corrected. The bias corrections can also be applied at different height levels, and three experiments were performed with bias corrections in the troposphere only, TropBC, stratosphere only, StratBC, and full atmosphere, FullBC (details in Table 1). The critical difference between the nudged and bias corrected runs is that when the model is  
75 nudged it is very tightly constrained towards observations, whereas when the bias corrections are applied the model can still respond realistically to perturbations. Additional details of the bias correction scheme are available in Tyrrell et al., (2020) and Tyrrell and Karpechko, (2021).

## 2.2 El Niño and La Niña experiments

80 Simplified ENSO SST sensitivity experiments were performed using the bias corrected climatologies as described in Tyrrell and Karpechko, (2021). For the ENSO SST pattern we used a regression of the Niño3.4 time series and HadISST SSTs from 1979–2009. Only the positive regression values between 30°S and 30°N and east of 150°E in the Pacific Ocean were used, and the regression values were multiplied by 1.5 to strengthen the response, corresponding to an El Niño or La Niña forcing magnitude of 1.5K. Climatological SSTs using HadISST data from 1979–2009 were used outside the tropical Pacific, and for  
85 the control run (CTRL). The ENSO anomaly was kept constant in time, i.e., the anomaly did not vary seasonally, and each experiment was run for 100 years.

The ERA5 Reanalysis data from 1979–2019 (Hersbach et al., 2020) was used as a reference to compare to the model results. El Niño and La Niña years were defined by the DJF value of the Oceanic Niño of ERSST.v5 SST anomalies in the Niño 3.4 region (5N–5S, 120–170W), from the NOAA CPC website (  
90 [https://origin.cpc.ncep.noaa.gov/products/analysis\\_monitoring/ensostuff/ONI\\_v5.php](https://origin.cpc.ncep.noaa.gov/products/analysis_monitoring/ensostuff/ONI_v5.php), last

access: 16 June 2021), and using a threshold of +/- 0.5K. This results in 15 El Niño years with 9 SSWs, 13 La Niña years with 11 SSWs, and 13 neutral years with 6 SSWs. The relatively low number of El Niño/La Niña years and SSWs means that few of the reanalysis ENSO results have statistical significance, and they may be dependent on the temperature threshold for defining ENSO events. As such, the reanalysis is included as a reference, but a more in depth analysis focusing  
95 on ERA5 – and other observational data sets – would be required to fully verify and explain those results.

The SSW central date is defined using the Charlton-Polvani criteria (Charlton and Polvani, 2007), defined as the first day when zonal mean zonal wind at 60N and 10hPa ( $uz_{60}$ ) is easterly (i.e.  $uz_{60} < 0$  m/s). The reversal has to occur during 1st November - 31st March. After an SSW has been detected, winds must return to westerlies for 20 consecutive days before another SSW is detected (as in Butler et al. 2017), and  $uz_{60}$  must return to westerlies for at least 10 consecutive days before  
100 30 April.

## 3 Results

### 3.1 Reduced model biases and mean ENSO response

The bias corrections are applied globally at different pressure levels. The reductions in biases have a three-dimensional structure which has relevance to the ENSO teleconnection to the stratospheric vortex and the Northern hemisphere, and this  
105 was explored in Tyrrell and Karpechko (2021). As this paper focuses on SSWs, the reduced model biases in the wintertime polar vortex are of particular interest. In Figure 1a we show the seasonal progression of  $uz_{60}$  using the mean daily values for the 100 year model runs, and 41 years of ERA5 data. The standard deviation for ERA5 and CTRL is also shown as shading. The CTRL run (blue) has a too weak vortex compared to ERA5 from October to January, and this bias is reduced by approximately half in the FullBC and StratBC runs. The bias corrections in TropBC actually increase the bias in the polar

110 vortex in November-December. All model runs effectively capture the polar vortex strength during February and March. As  
shown in Figure 1 b the interannual variability of the vortex strength is relatively well simulated in CTRL, and the bias  
corrections do not significantly change the variance. The largest difference between the reanalysis and the model is in  
January when ERA5 exhibits increased variance, which is not simulated by any of the model runs. The mean difference in  
daily  $uz_{60}$  between El Niño and neutral years, and La Niña and neutral years is shown in Figure 1 c and d for the model (i.e.  
115 daily mean of 100 El Niño or La Niña years minus 100 neutral years), and ERA5 (15 El Niño years, 13 La Niña years, minus  
13 neutral years). The CTRL, FullBC and StratBC runs have the strongest mean El Niño response throughout winter,  
although only the StratBC has a statistically significant response in January (as shown at the 5% level by bold lines). The  
CTRL and FullBC show a weaker response in January. The TropBC has only a weak El Niño response throughout winter.  
The CTRL has the weakest La Niña response and the StratBC the strongest with a persistent response from December to  
120 March. The mean daily ERA5 response to both El Niño and La Niña shows large variability with little significance in the  
response. For certain months the ERA5 response is opposite to that seen in the models, e.g. the February-March La Niña  
response, and at times it shows a similar magnitude and sign, e.g. the La Niña response in January or the El Niño response in  
March. The mean ENSO response was studied in more detail in Tyrrell and Karpechko (2021), where seasonal mean values  
indicated that in early winter the models and ERA5 disagreed on sign of the El Niño response and agreed on the La Niña,  
125 then in late winter they agreed on the El Niño response and disagreed on La Niña.

Before analyzing SSW responses we assess the ability of the model to capture the timescales of variability. This is explored  
in Figure 2, following Fig. 1 from Baldwin et al., 2003. Using the geopotential height averaged over the polar cap (60N –  
90N) (Zcap), and at pressure levels from 1000hPa to 1hPa, the figure shows the time in days when the autocorrelation  
130 function drops to  $1/e$ . The day-to-day variability is smoothed with a Gaussian filter ( $\sigma = 26$  days). The CTRL run captures  
the timescales of the variability in the winter stratosphere reasonably well, but it is slightly too weak in early winter. The  
timescales are shorter in the FullBC, and again in TropBC runs, and are slightly longer in StratBC. In all experiments, the  
timescales are shorter in El Niño experiments and longer in La Niña experiments than in the corresponding neutral  
experiments. The relationship between the strength of the polar vortex and the timescales of variability was tested in Figure  
135 3, which plots the DJF UZ 60N 10hPa against the DJF timescales of variability averaged from 150hPa to 50hPa. Figure 3a  
shows each ENSO phase for each model separately, so a weaker or stronger vortex strength may be due to the ENSO phase  
or the bias corrections. A stronger vortex corresponds to longer timescales of variability, and a weaker vortex corresponds to  
shorter timescales, with a correlation coefficient of  $r = 0.62$ . We examine this more closely in Figure 3b by averaging each  
ENSO phase (i.e. the mean of CTRL\_EN, FullBC\_EN, TropBC\_EN, and StratBC\_EN, etc. El Niño is up-triangles, La Niña  
140 is down triangles and neutral is the circles), and each bias corrected run (i.e. the mean of FullBC, FullBC\_EN, FullBC\_LN.  
Colored crosses). We see that as the vortex strengthens and weakens by ENSO phase, the timescales of variability change  
accordingly. However, changes to the vortex strength due to the bias corrections do not correspond neatly to changes to  
timescales of variability. A stronger vortex has weaker dynamical variability and is driven by slow radiative processes,

145 which may explain the vortex-variability timescales relationship between ENSO phases. On the other hand, at least in the  
case of CTRL-FullBC, the relationship does not hold, because FullBC has both stronger vortex and shorter variability;  
therefore, application of the bias correction technique may have affected the timescales of the variability.

### 3.2 SSW statistics

150 The statistics of SSWs are detailed in Table 1. The number of SSWs per year is overestimated in CTRL (1.11 SSWs/year) in  
comparison to ERA5 (0.65 SSWs/year). This statistic is made more realistic in FullBC (0.70 SSWs/year), but there is only a  
small improvement in the StratBC (1.03 SSWs/year) and TropBC (1.09 SSWs/year) runs. Consistent with previous modeling  
studies (e.g. Polvani et al. 2017), SSW frequency is increased during El Niño years and decreased during La Niña years in all  
model experiments. For all model experiments, except TropBC, the number of SSW during El Niños is nearly twice as large  
as that during La Niñas. In TropBC, the exceedance is 40%. For ERA5 we find that SSW frequency is increased during both  
El Niños and La Niñas, consistent with previous studies.

155 The seasonal evolution of SSWs frequency is shown in Figure 4. To explore the differences in seasonal evolution more  
clearly, the number of SSWs in each month is divided by the total number of SSWs for each experiment, similarly for ERA5.  
This gives the percentage of the annual total SSWs in each month. Compared to ERA5 there is not enough seasonal variation  
in CTRL, with too many SSWs in November, December, and March, and too few in January and Feb. The seasonal variation  
is improved slightly in FullBC, although the seasonal cycle is still underestimated. In StratBC and TropBC the SSW  
160 seasonal statistics are not improved as much as in FullBC. In particular, TropBC almost has an inverse of the seasonal  
relationship of SSWs compared to ERA5, with the most SSWs in November. There are no consistent changes to the  
seasonality of SSWs with El Niños or La Niñas.

### 3.3 SSW downward propagation and surface response

165 Figure 4 shows the SSW composite of normalized Zcap, and then the anomalous values in El Niño an La Niña years relative  
to neutral years. For ERA5 the ENSO phases are normalized using the standard deviation for all years. The CTRL run  
simulates the downward propagation of stratospheric anomalies after an SSW reasonably well, although it underestimates the  
tropospheric response in comparison to ERA5. For neutral years (Figure 4 d, g, j, m) the CTRL run has the weakest  
tropospheric response, and the FullBC run has the strongest, and is most similar to ERA5. All runs show a weaker  
stratospheric response during El Niño years in comparison to neutral years, both before and after SSWs (i.e. Figure 4 e, h, k,  
170 n), and this corresponds to a slightly weaker tropospheric response. Conversely, the models show a stronger stratospheric  
response during La Niña years (Figure 4 f, i, l, o). In FullBC and StratBC in particular, this corresponds with a strong  
tropospheric response. The ENSO response in ERA5 varies from the models. During El Niño years there is a stronger  
response (relative to neutral years) before SSW events, with a slightly stronger stratospheric response and weaker  
tropospheric response after SSW events. Whereas during La Niña years the normalized Zcap response is weaker before, and  
175 stronger after SSW events.

The sea level pressure response to SSWs is well represented in all model experiments and is similar across different climatologies, i.e. bias correction does not greatly affect the surface response. Figure 6 shows the composites of absolute sea level pressure anomalies averaged over 30 days after the central dates of SSWs, and the differences between this quantity in El Niño minus neutral years (middle column), and La Niña minus neutral years (right column). A negative Arctic Oscillation (AO) pattern following SSWs is seen in all runs. The negative AO pattern is stronger in La Niña experiments for the FullBC and StratBC runs, which relates to the stronger stratospheric Zcap response in Figure 4 i and o. The weaker Zcap response in Figure 4 during El Niño years can also be seen in the weaker negative AO response in CTRL and TropBC, but not FullBC or StratBC (Figure 6 e, h, k, n). The 2-meter temperature response was expected to be quite weak in the model runs, since the same climatological SSTs were used for all runs (except SST anomalies prescribed in tropical Pacific in El Niño and La Niña experiments) which dampens the near surface temperature anomalies, however, there was a La Niña – El Niño difference of 0.4K across Eurasia in the monthly averaged 2-meter temperature (not shown).

### 3.4 Heatflux and wave 1/wave 2 response

We now look at the wave forcing that causes SSWs. Figure 7 shows the SSW composite anomalies for the heat flux at 100hPa, 45N-75N. The black lines show all wave numbers, the red lines are wave 1, and the blue lines are wave 2. Solid lines indicate significance at the 90% confidence level. The ratios of wave 1 to wave 2 SSW events are also listed in Table 1, where each event is defined based on the average heat flux for the 10 days preceding an SSW. The CTRL run has too small wave1/wave2 flux ratio of 62/38 compared to the ERA5 ratio of 77/23, i.e. there are too many wave 2 events in CTRL; ERA5 has 0.15 wave 2 SSWs per year, and CTRL has 0.41 wave 2 SSWs per year. This ratio is improved in the bias correction experiments, with the FullBC (76/24) being most similar to ERA5, and a smaller improvement in StratBC (67/33) and TropBC (68/32). As expected, in ERA5 the wave 2 flux is weaker in El Niño years and stronger in La Niña years, hence, La Niña events have a smaller wave 1/wave 2 ratio than El Niño events (e.g. Garfinkel & Hartmann, 2008). This is simulated reasonably well in the experiments, but the relationship is weaker. For all climatologies the El Niño years have a larger wave 1/wave 2 ratio than La Niña years, however, in CTRL the La Niña experiment has a larger wave 1/wave 2 ratio than the neutral experiment. The total heat flux anomaly before an SSW is smallest in El Niño and largest in La Niña in all climatologies. Since the anomalies are calculated with respect to each experiment's own background flux, which is largest in El Niño and smallest in La Niña experiments, the result explains the larger frequency of SSWs in El Niño and small frequency in La Niña. It happens because during El Niños, an SSW can be induced by a weaker wave activity pulse which happen more frequently; however, a larger wave activity pulse that occurs more rarely is required to induce an SSW during La Niñas. Note that in all experiments as well as in ERA5 the larger flux during La Niñas is due to increased wave 2 contribution; however, only in StratBC the wave 2 increase is larger than that of wave 1, which is also seen in ERA 5.

#### 4 Discussion and Conclusions

The ECHAM6 atmospheric model was run with bias-correcting tendencies added to the temperature and divergence at each timestep. The bias corrections were added at different levels – the stratosphere (StratBC), troposphere (TropBC), or the full atmosphere (FullBC) – to create a range of climates with reduced biases. SST forcing experiments were conducted within these climates by applying a positive or negative ENSO pattern in the tropical Pacific. The seasonal mean response is explored in Tyrrell and Karpechko (2021) and in this paper we have focused on the relationship between the ENSO forcing and SSWs.

For the years without an ENSO forcing the number of SSWs is overestimated in our control run in comparison with ERA5. This is largely due to the polar vortex being too weak in the CTRL run. When the strength of the vortex is improved in the FullBC the SSW statistics also improve. There is a smaller improvement in the StratBC runs, despite the improvement in the strength of the vortex being similar to FullBC. The polar vortex remains weak in the TropBC run, and there is no significant improvement in the number of SSWs. The lack of stratospheric bias correction in TropBC indicates that the stratospheric biases do not originate in the tropospheric circulation biases but are more likely resulting from parameterizations. The seasonal variation of SSWs is too small in the CTRL run compared to ERA5, with too many SSWs in November and March. This is slightly improved in FullBC, but not in StratBC or TropBC. The duration of an SSW is well simulated, i.e. the number of days that  $UZ < 0$  m/s after an SSW is not significantly different from ERA5 in any of the model runs suggesting that it is controlled by basic processes such as radiative relaxation, well represented in the model. Likewise, the downward propagation and surface response is similar between ERA5 and the control run, and not affected by the bias corrections. The ratio of wave 1 to wave 2 events is too small in CTRL, and this is improved in FullBC, and to a lesser extent in StratBC and TropBC.

The ERA5 reanalysis data suggests that there is an increase in SSWs in both La Niña and El Niño years, when compared to neutral years (Table 1). This is based on a fairly low number of events; depending on the threshold used to define ENSO there are around 10-15 El Niño or La Niña years, with around 0.6 – 0.9 SSWs per year. This makes it difficult to statistically confirm the observed ENSO-SSW relationship. Our model results differ from observations and are in line with other modelling studies, which show a more linear relationship between ENSO and SSWs. The increase in wave 1 events in El Niño years and wave 2 events in La Niña years is captured by the bias corrected runs, but not by the control run. The timescales of variability in the stratosphere were tested with the autocorrelation of Zcap, and it was found that the weakening (El Niño) and strengthening (La Niña) of the polar vortex due to ENSO phases explained changes to the timescales of the variability. However, similar strength changes to the vortex by the bias corrections did not relate directly into similar changes to the timescales of the variability, suggesting that other factors associated with bias correction procedure affect the timescales.

The impact of ENSO phase on Zcap response to SSWs was fairly consistent amongst the models, with a weaker lower stratospheric Zcap SSW relative response (i.e. less warming/less weakened vortex) during El Niño years, and stronger Zcap

relative response (more warming, weaker vortex) during La Niña years. This relationship between ENSO phase and the  
240 stratospheric SSW response did not consistently lead to a similar relationship between the MSLP response averaged over 30  
days after SSWs amongst the models. All the model runs showed a negative AO response, with FullBC and StratBC having  
a stronger response in La Niña years and CTRL and TropBC having a weaker response in El Niño years. The composite HF  
showed that a larger anomalous wave forcing is required for an SSW during La Niña years, compared to neutral and El Niño  
years, and the El Niño anomalous wave forcing was slightly smaller than in neutral years. This relationship is associated  
245 with the fact that the anomalous forcing is calculated with respect to each experiments own climatology, and there is a larger  
background wave forcing in the El Niño experiments and a smaller wave forcing in the La Niña experiments. Consequently,  
a relatively small anomalous forcing is required to induce an SSW in the El Niño experiments, and a large anomalous  
forcing is required in La Niña experiments. The additional wave forcing during La Niña years primarily came from an  
increase in wave 2 events, and likewise the reduced wave forcing during El Niño years was associated with less wave 2  
250 forcing. This result is similar in the ERA5 data, although with more extreme differences in wave 1 and 2 between the ENSO  
phases. Indeed, in ERA5 La Niña years the magnitude of wave 2 forcing is greater than that of wave 1, which only occurred  
in the StratBC model runs.

Overall, we show that improvements to the strength of the polar vortex can improve the SSW statistics of a model in relation  
to the number of SSWs per year, and the ratio of wave 1 and wave 2 events. Whether the improvements leads to a more  
255 realistic ENSO-SSW relationship is unclear given the large uncertainty in the observed statistics.

### Data availability

Data availability. The climatological means of all model experiments for the variables used in this paper are available  
at <https://doi.org/10.6084/m9.figshare.13311623.v2> (Tyrrell and Karpechko, 2020). The full time series is available upon  
request to Nicholas Tyrrell. ERA-Interim and ERA5 data can be found at Copernicus Climate Change Service Climate Data  
260 Store (CDS, <https://doi.org/10.24381/cds.bd0915c6>, Hersbach et al., 2018). The ECHAM6 model is available to the  
scientific community under a version of the MPI-M license <http://www.mpimet.mpg.de/en/science/models/license/> (Max-  
Planck-Institut für Meteorologie, 2020). The HadISST SST and sea ice data are available from the U.K. Met Office  
<https://www.metoffice.gov.uk/hadobs/hadisst/> (Met Office Hadley Centre, 2020; Rayner et al., 2003).

### Author Contributions

265 JK conducted analysis and contributed to the manuscript, NLT conducted the model runs and analysis and wrote the first  
draft. AYK contributed to the interpretation of the results and improving the final manuscript.

### Competing interests.

The authors declare that they have no conflict of interest.

### Acknowledgments

270 The authors would like to acknowledge Sebastian Rast, John Scinocca, Slava Kharin, and Michael Sigmond for invaluable technical and scientific help.

### Financial support.

This research has been supported by the Academy of Finland (grant nos. 286298, 333255, and 294120).

**Table 1.** Experiment names and details for bias correction and ENSO experiments. Number of SSWs per year calculated from 100 years in the model experiments, and 41 years of ERA5 data. For ERA-5, the SSW frequency in the third column is shown for all years and only for years with a neutral ENSO in brackets. The wave1:wave2 ratio is based on the heatflux at 100hPa, 45N-75N.

Bias corrections	Experiment	Neutral		El Niño		La Niña	
		SSW/yr	wave1:wave2	SSW/yr	wave1:wave2	SSW/yr	wave1:wave2
-	ERA5	0.67 (0.46)	77:23	0.60	100:0	0.85	45:55
None	CTRL	1.12	62:38	1.66	70:30	0.81	70:30
850-2.6 hPa	FullBC	0.71	76:24	1.07	71:29	0.58	62:38
100-2.6 hPa	StratBC	1.04	67:33	1.38	74:26	0.72	51:49
850-100 hPa	TropBC	1.10	68:32	1.23	75:25	0.86	60:40

**Figure 1:** a) Mean daily zonal mean zonal winds at 60°N and 10hPa for ERA5 (1979-2019) and control and bias-correction experiments (100 years each). Shading shows one standard deviation for ERA5 (grey) and CTRL (blue). b) Mean daily standard deviation for ERA5 and the experiments. c) Daily  $uz_{60}$  El Niño response calculated as El Niño years minus neutral years, e.g. CTRL\_EN – CTRL. c) Daily  $uz_{60}$  La Niña response calculated as La Niña years minus neutral years.

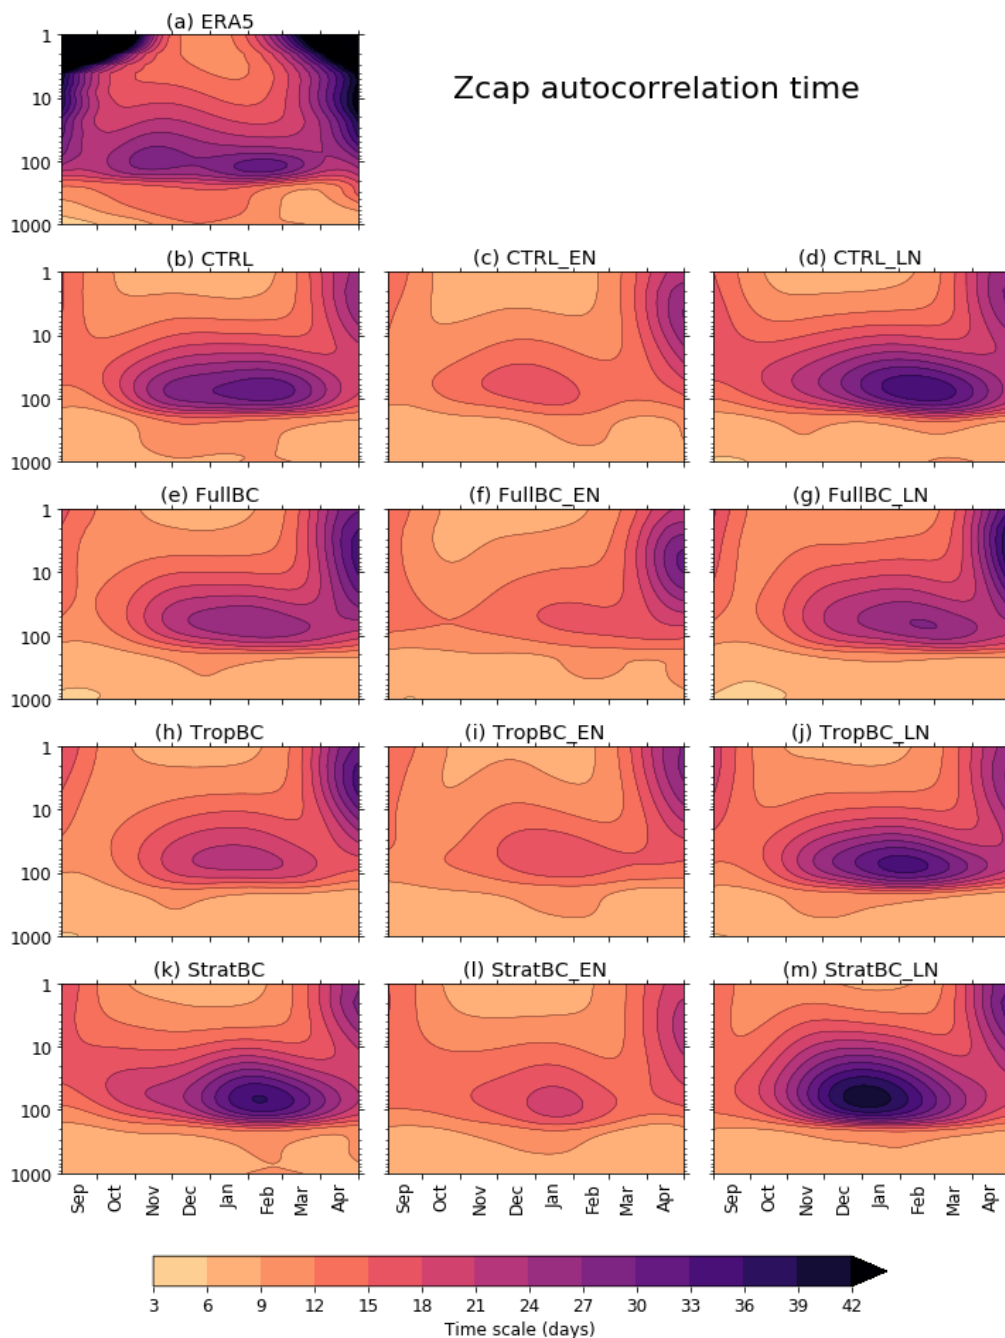

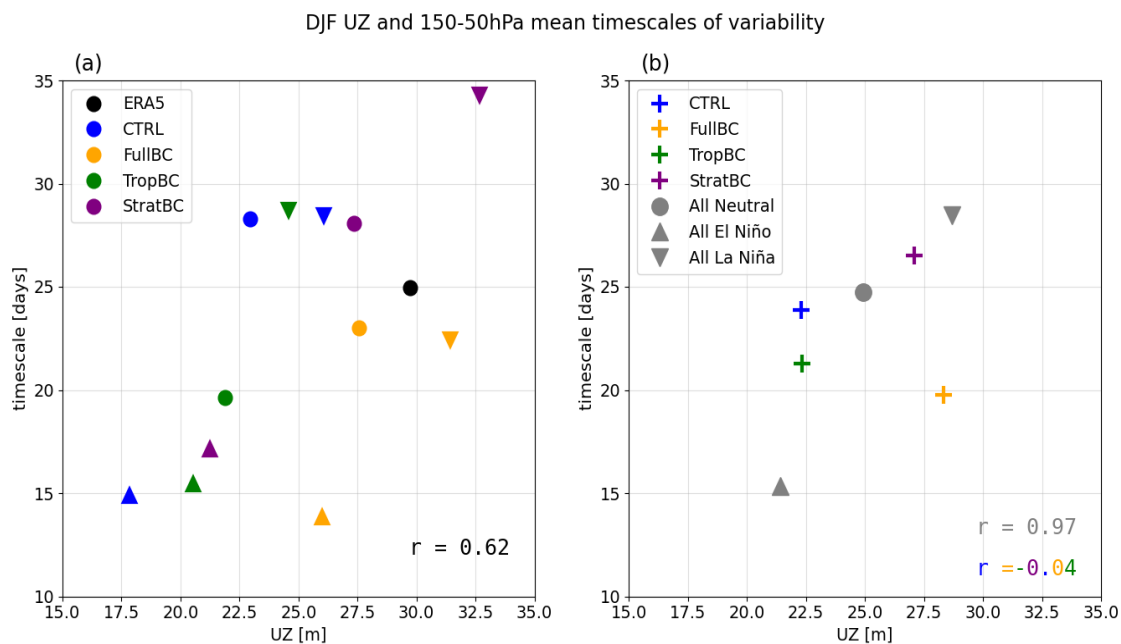

Figure 2: Time-scales of polar cap (60°N-90°N) geopotential height (Zcap), time for the autocorrelation function to drop to 1/e, smoothed in time with a Gaussian filter ( $\sigma = 26$  days), following Fig. 1 from Baldwin et al. 2003. ERA5 data from 1979-2019, 100 years for each model run (neutral, El Niño, and La Niña).

375

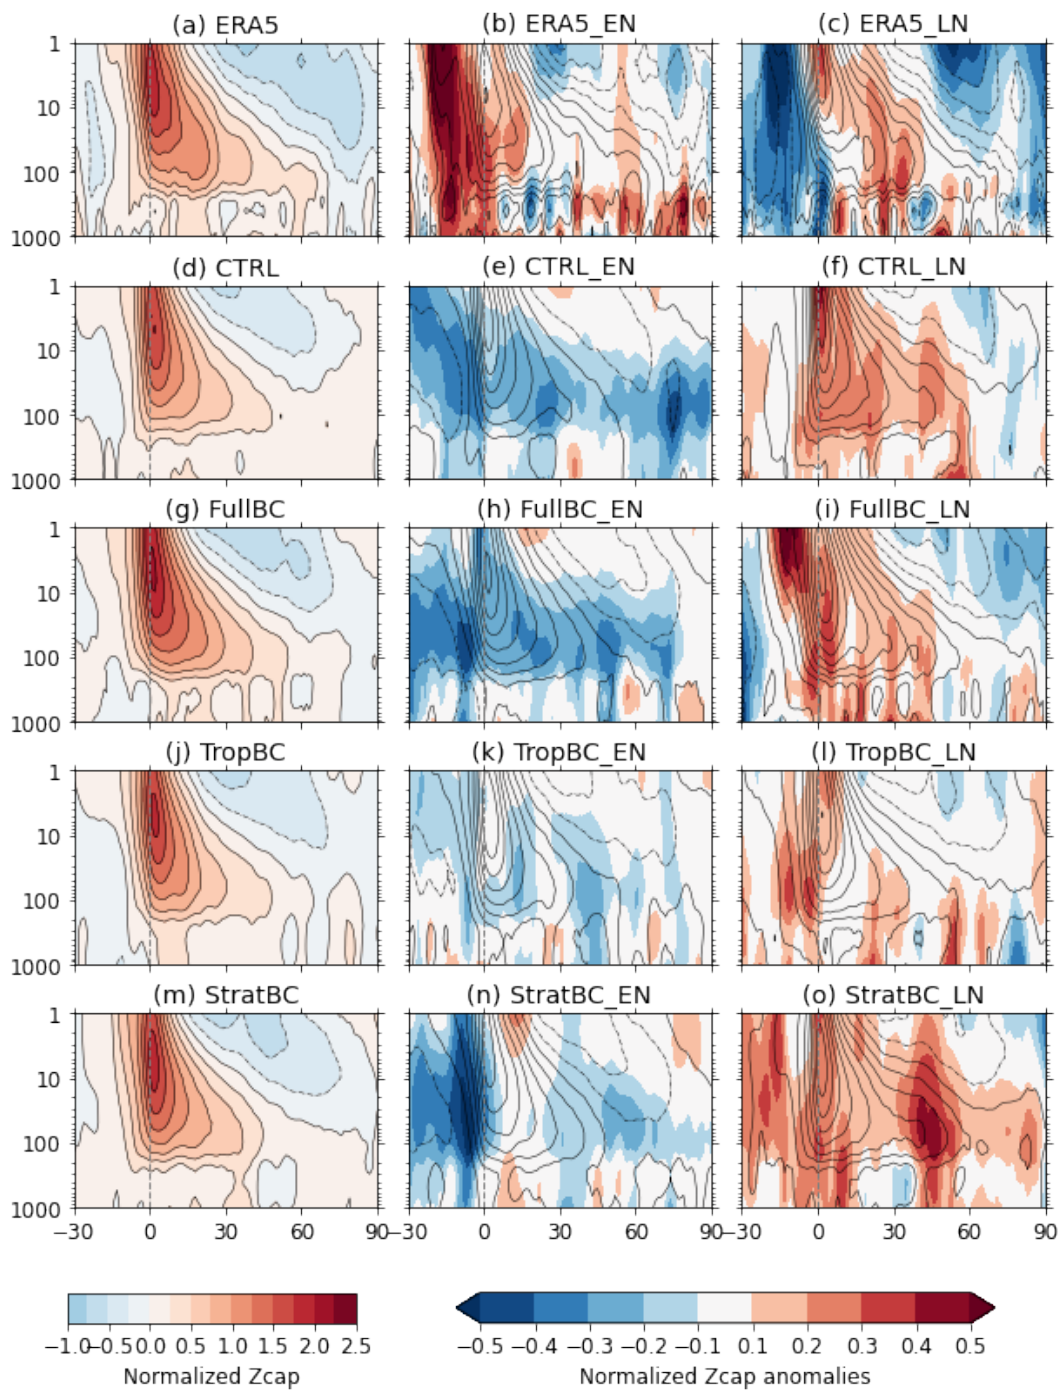

380

**Figure 3: Mean DJF zonal mean zonal wind at 60°N 10hPa plotted against weighted average from 50-150hPa of time-scales of polar cap geopotential height (Zcap) from Figure 2. (a) Circles are neutral ENSO conditions, upward-triangles are El Niño, downward-triangles are La Niña. Correlation coefficient for all models and ENSO phases:  $r = 0.62$  (b) Colored crosses show the mean of El Niño, La Niña and neutral conditions for each experiment (corr. coef.:  $r = -0.04$ ). Grey circle and triangles show the multi-model mean for each ENSO phase (corr. coef.:  $r = 0.97$ ). ERA5 data from 1979-2019, 100 years for each model run (neutral, El Niño, and La Niña).**

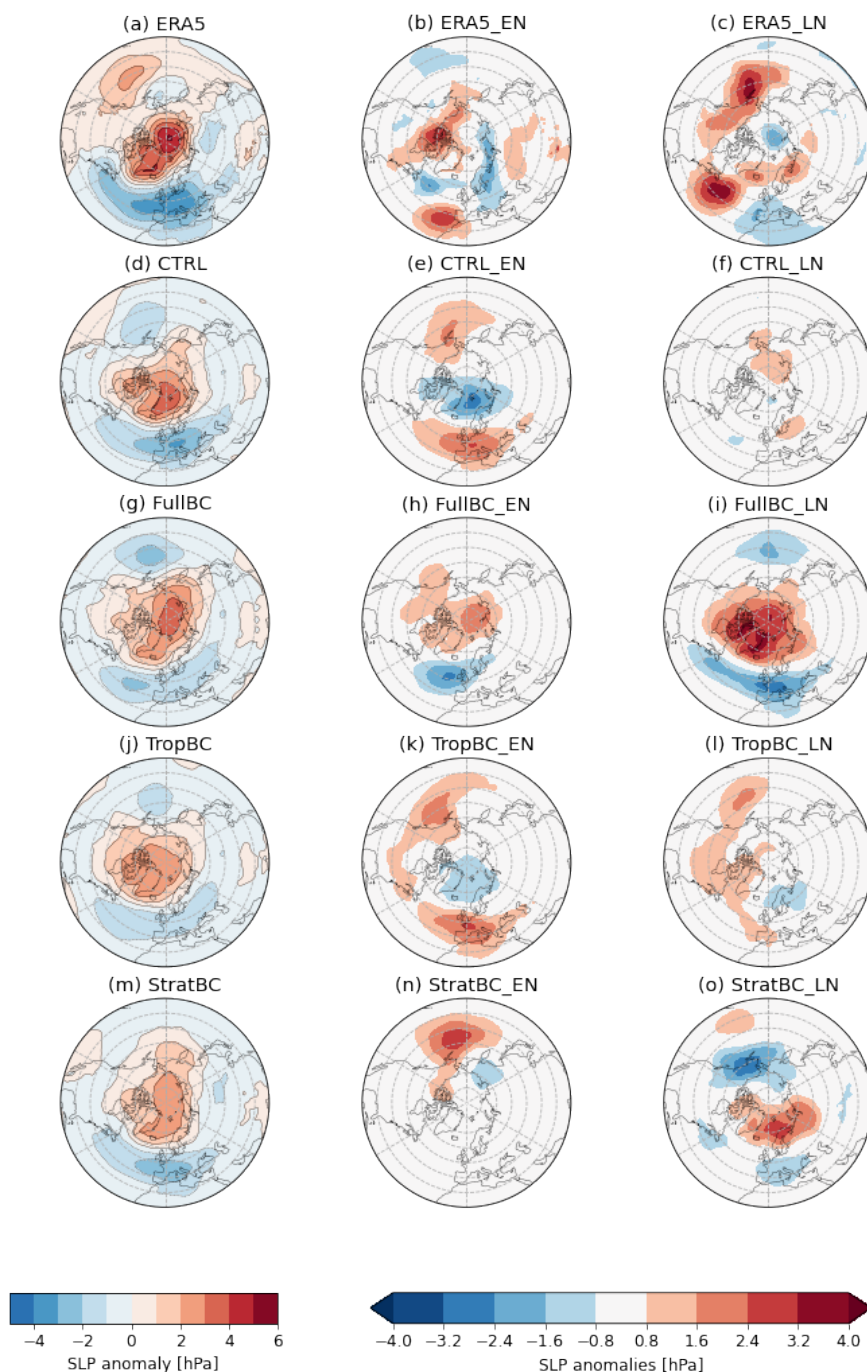

**Figure 4: Monthly distribution of SSWs, for neutral, El Niño and La Niña years. The bars are normalized by dividing the number of SSWs in each month by the total number of SSWs for each experiment. ERA5 data from 1979-2019, 100 years for each model run (neutral, El Niño, and La Niña).**

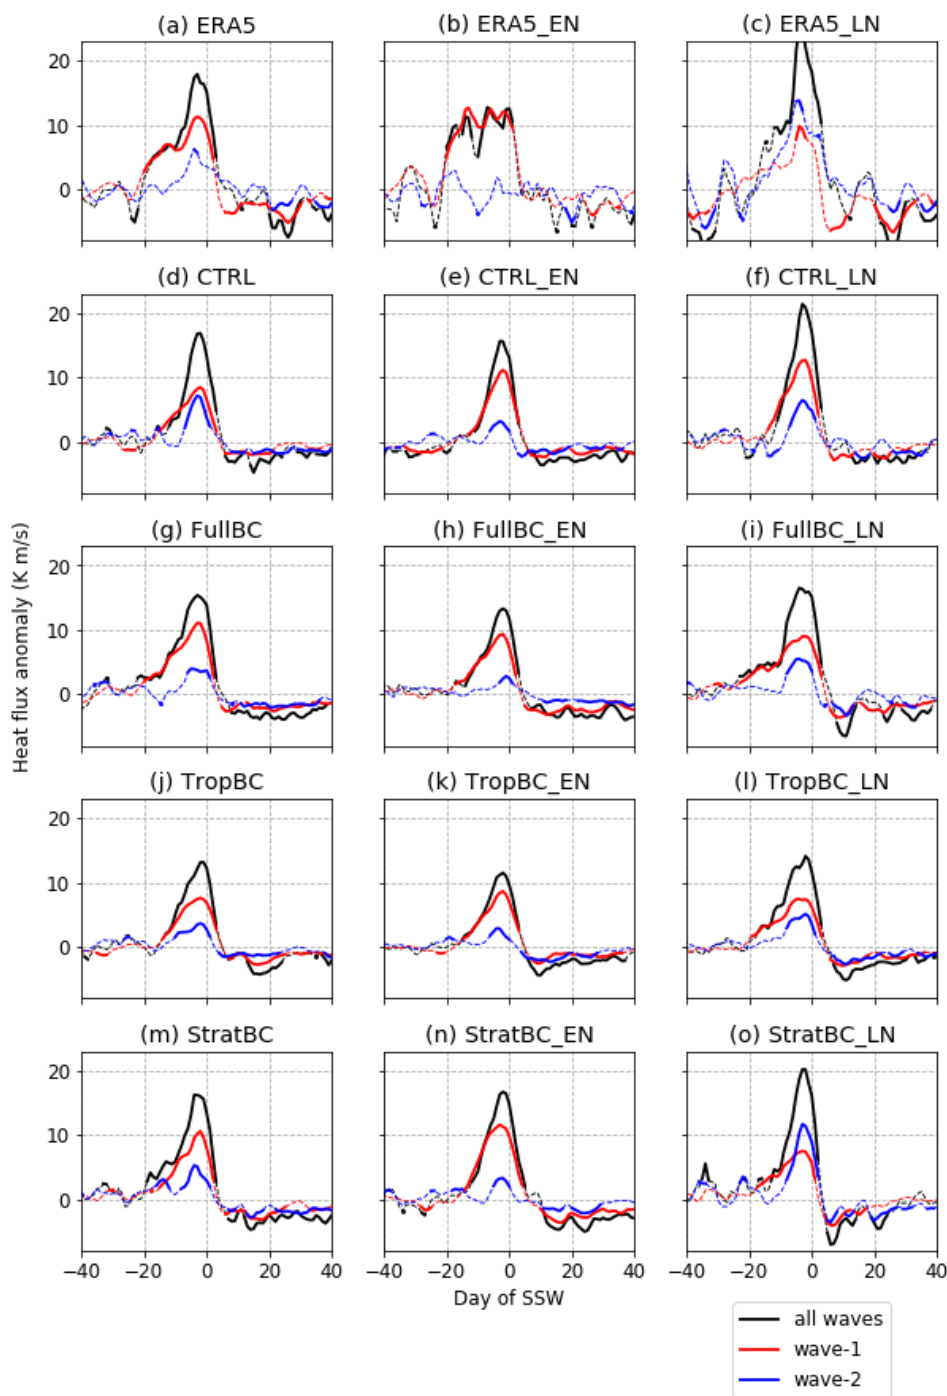

395

Figure 5: SSW response of normalized polar cap ( $60^{\circ}\text{N}$ - $90^{\circ}\text{N}$ ) geopotential height, composited around day zero (shown as dashed vertical grey line). Left column shows neutral years for the experiments and all years for ERA5, middle column shows SSW response in El Niño years with contours (negative values dashed) and the El Niño anomalous SSW response in colours (normalized polar cap geopotential height in El Niño years minus neutral years), and right column is the same for La Niña. ERA5 data from 1979-2019, 100 years for each model run (neutral, El Niño, and La Niña).

400 **Figure 6: Left column: Composites of absolute SLP anomalies averaged over 30 days after the central dates of SSWs, for neutral ENSO conditions for the models and all years for ERA5. Middle and right column show difference between SLP anomalies during El Niño (middle) and La Niña (right), minus neutral condition anomalies. ERA5 data from 1979-2019, 100 years for each model run (neutral, El Niño, and La Niña).**

405 **Figure 7: Heat flux anomaly at 100hPa, 45°N-75°N for SSW events composited on day zero of SSWs, defined for wave 1 (red), wave 2 (blue) and all waves (black). In model experiments, the anomalies are calculated with respect to that experiment’s climatology. In ERA-5, the anomalies for all years as well as for ENSO years are calculated with respect to the ERA-5 climatology. ERA5 data from 1979-2019, 100 years for each model run (neutral, El Niño, and La Niña).**
