**Abstract.** The synoptic dynamics leading to the longest wet spells in Europe are so far poorly investigated, despite these events' potentially large societal impacts. Here we examine the role of cyclones and potential vorticity (PV) cutoffs for unusually long wet spells in Europe, defined as the 20 longest uninterrupted periods with at least 5 mm daily accumulated precipitation at each ERA-Interim grid point in Europe (this set of spells is hereafter referred to as  $\mathcal{S}_{20}$ ). The  $\mathcal{S}_{20}$  occur predominantly in summer over the eastern continent, in winter over the North Atlantic, in winter or fall over the Atlantic coast, and in fall over the Mediterranean and European inland seas. Four case studies reveal distinct archetypal synoptic storylines for long wet spells: (a) A seven-day wet spell near Moscow, Russia, is associated with a single slow-moving cutoff-cyclone couple; (b) a 15-day wet spell in Norway features a total of nine rapidly passing extratropical cyclones and illustrates serial cyclone clustering as a second storyline; (c) a 12-day wet spell in Tuscany, Italy, is associated with a single but very large cutoff-complex, which is replenished multiple times by a sequence of recurrent anticyclonic wave breaking events over the North Atlantic and western Europe; and (d) a 17-day wet spell in the Balkans features intermittent periods of diurnal convection in an environment of weak synoptic forcing and recurrent passages of cutoffs and thus also highlights the role of diurnal convection for long wet spells over land. A systematic analysis of cyclone and cutoff occurrences during the  $\mathcal{S}_{20}$  across Europe reveals considerable spatial variability in their respective role for the  $\mathcal{S}_{20}$ . For instance, cyclones are present anywhere between 10% and 90%, and cutoffs between 20% and 70% of the  $\mathcal{S}_{20}$  time steps, respectively, depending on the geographical region. However, overall both cyclones and cutoffs appear in larger number and at a higher rate during the  $\mathcal{S}_{20}$  compared to climatology. Furthermore, in the Mediterranean, the cutoffs and cyclones are significantly more persistent during the  $\mathcal{S}_{20}$  compared to climatology. Our study thus documents for the first time the palette of synoptic storylines accompanying unusually long wet spells across Europe, which is a prerequisite for developing an understanding of how these events might change in a warming climate and for evaluating the ability of climate models to realistically simulate the synoptic processes relevant to these events.

## 1 Introduction

30 The nature of precipitation is episodic. In Europe, precipitation episodes vary strongly regarding peak and mean precipitation rates as well as duration. Unusually large peak precipitation rates, often termed *precipitation extremes*, have received much attention in the atmospheric dynamics community, and the synoptic-scale dynamical processes leading to precipitation extremes have been studied in detail for precipitation extremes on a wide range of time-scales, from minutes (e.g. Lenderink and Van Meijgaard, 2010) to seasons (e.g., Flaounas et al., 2020). Research on extreme precipitation is often motivated by  
35 these events' relevance for a wide range of natural hazards such as landslides and flooding (e.g., Moore et al., 2012; Rössler et al., 2014; de Vries, 2021). However, studies on individual high-impact events often report an extended duration of the event, for instance four consecutive days of heavy rain leading to the record floods in Germany in early summer 2013 (Grams et al., 2014), a sequence of multi-day precipitation episodes causing the devastating Pakistan flood in summer 2010 (Martius et al., 2013), or a temporal clustering of wet periods leading to an emergency spill-over of California's Oroville Dam in February  
40 2017 and mass evacuation of the population living downstream (White et al., 2019; Moore et al., 2020). Clearly, in addition to peak intensities, the temporal characteristics of precipitation episodes are thus highly relevant too.

Previous studies have assessed these characteristics often by focusing on continuous or quasi-continuous episodes of precipitation, so called *wet spells* (e.g., Berger and Goossens, 1983; Schmidli and Frei, 2005; Tolika and Maheras, 2005; Zolina et al., 2010, 2013). For example, Zolina et al. (2013) found that the mean duration of wet spells in Europe over the last 60  
45 years is between 1.5 days over the Ukraine and southern Russia and 5 days over the Scandinavian Atlantic coast. They reported that the longest wet spells last between 3 (eastern Europe) and 12 days (Scandinavia). It should be noted that these durations depend on the specific definition of wet spells. Furthermore, they found an increasing duration of wet spells during the last 60 years, especially over northern and central Europe, and a slightly decreasing duration over southern Europe during the cold  
50 seasons. In Scandinavia and eastern Europe, the duration of wet spells decreased significantly during the warmer seasons. Schmidli and Frei (2005) focused on observational data from Switzerland and identified seasonally and regionally varying trends in the duration of the longest wet spells per year. However, despite a considerable body of literature on statistical characteristics of wet spells, the synoptic-scale dynamical mechanisms leading to precipitation episodes with an unusually long duration – typically one to two weeks – have so far not been investigated in detail.

55 For midlatitude extreme precipitation events on timescales from a few hours to a few days it is well known that a range of weather systems, which often occur jointly, can serve as dynamical precursors. These are extratropical cyclones (Ulbrich et al., 2003; Field and Wood, 2007; Pfahl and Wernli, 2012), fronts (Catto and Pfahl, 2013; Rüdüsühli et al., 2020), so-called “warm conveyor belts” (WCBs; Pfahl et al., 2014), long-range horizontal moisture transport (Winschall et al., 2014), often in  
60 the form of so-called “atmospheric rivers” (Zhu and Newell, 1998; Ralph et al., 2004; Lavers and Villarini, 2013), upper-level short-wave troughs and cutoffs (Massacand et al., 1998; Martius et al., 2006), and even atmospheric blocks (Sousa et al., 2017;

Lenggenhager and Martius, 2019). Given their dynamical relationship and interactions, it is often the combination of these weather systems that leads to an extreme precipitation event (de Vries, 2021). For instance, a narrow upper-level trough is often linked to an elongated surface cold front and intense poleward moisture transport, along which frontal-wave cyclogenesis and the subsequent formation of a WCB can occur. All of these weather systems act in concert to produce the heavy precipitation.

The mechanisms and weather systems contributing to the occurrence of unusually long-lasting wet spells are far less clear. Few studies investigated the causes of long-lasting precipitation episodes and mostly focused on multi-day heavy precipitation events rather than (potentially even much longer) wet spells. Moore et al. (2021) investigated multi-day (i.e., longer than 3 day) episodes of heavy precipitation along the North American west coast and argued that, on a general level, multi-day heavy precipitation events either occur when individual rain producing weather systems stall or when multiple such weather systems occur in a serially clustered manner.

In particular in the North Atlantic region, serial clustering of extratropical cyclones is well documented (Mailier et al., 2006; Pinto et al., 2014; Priestley et al., 2017a, b; Dacre and Pinto, 2020). This phenomenon occurs predominantly at the downstream end of the North Atlantic storm track (Mailier et al., 2006; Dacre and Pinto, 2020) and arises over western Europe preferentially when the North Atlantic jet is extended towards Europe, remains at a similar latitude for a prolonged period (typically more than a week) and thereby steers entire cyclone families (i.e., primary cyclones as well as frontal wave cyclones forming on trailing cold fronts of the primary cyclones) into the same region (Pinto et al., 2014; Priestley et al., 2017a; Dacre and Pinto, 2020). During such clustering periods, the jet is kept in place by momentum fluxes arising from cyclonic and anticyclonic Rossby wave breaking on the poleward and equatorward side of the jet, respectively. The process of serial cyclone clustering is clearly relevant for long precipitation episodes, as both the extremely wet winter 2013/14 in the United Kingdom and a large set of multi-day heavy precipitation episodes in California have been related to serial cyclone clustering (Priestley et al., 2017b; Moore et al., 2021).

The stalling of individual cyclones as well as upper-level flow features as the cause of long-lasting heavy precipitation events has also been documented in multiple cases, e.g., for an event in Spain (Doswell et al., 1998) when a single slow-moving cyclone associated with an upper-level cutoff caused a seven-day heavy precipitation event. Such cutoffs typically form from synoptic-scale Rossby wave breaking, during which upper-level troughs meridionally amplify to an extent where their evolution is no longer governed by linear wave dynamics and isentropic PV contours start to overturn (McIntyre and Palmer, 1983). Thereby, narrow and meridionally elongated filaments of stratospheric air (i.e., air with  $PV > 2$  PVU), so-called PV streamers (Appenzeller and Davies, 1992) form. As the wave breaking process continues, these PV streamers tend to break up into one or several PV cutoffs, which consist of stratospheric air that is cut-off from the main stratospheric air mass on lower isentropes, but remains connected to the stratosphere on higher isentropes (Portmann et al., 2021). Upper-level PV streamers

and cutoffs are accompanied by a cyclonic wind field with a far field effect down to the lower troposphere (Hoskins et al., 1985). Below such PV features the static stability is reduced, which can contribute to the occurrence of deep convection and heavy precipitation (Massacand et al., 1998; Romero et al., 1999; Martius et al., 2006; Portmann et al., 2018; Moore et al., 2019). Moreover, cutoffs in a baroclinic zone are associated with quasi-geostrophic forcing for ascent on their downstream side, cloud formation and precipitation, even if they remain stationary. Since some cutoffs are relatively long-lived and stationary, they can play an essential role in the formation of multi-day precipitation extremes (e.g. Grams et al., 2014). Thus, individual unusually stationary PV streamers and cutoffs also need to be considered as potential dynamical precursors of unusually long-lasting wet spells.

Furthermore, some recent studies have highlighted the role of recurrent upper-level dynamics for long-lasting wet periods. For example Lenggenhager et al. (2019) documented a case where recurrent PV streamer formation in association with an atmospheric block induced a prolonged wet period and flooding on the Alpine South side. Along a similar line of arguments Ali et al. (2021) showed that recurrent synoptic-scale Rossby wave packets [i.e., a succession of wave packets that are each in phase such that multiple troughs form repeatedly in the same region, see Röthlisberger et al. (2019) for details] significantly increase the duration of summer wet spells in parts of Central Europe and Iberia.

In summary, previous research focused on the statistics of wet spells or on the dynamics of short-term to multi-day heavy precipitation events, but rarely on the dynamical mechanisms responsible for unusually long-lasting wet spells. However, considering the potentially high societal impact of unusually long wet spells and the reported trend of increasing wet spell duration, it is crucial to improve our understanding of the dynamical processes that lead to these events. Previous studies clearly identified serial clustering of extratropical cyclones and stalling individual or recurrent upper-level cyclonic flow features (e.g., PV cutoffs) as key for multi-day heavy precipitation events. Here we hypothesize that extratropical cyclones and PV cutoffs also play an important role for the quasi-continuous precipitation during unusually long wet spells. Therefore, we pragmatically choose these two weather systems and examine their role for the formation of unusually long wet spells in Europe. Specifically, the purpose of this study is to identify unusually long wet spells in Europe using ERA-Interim reanalysis data (Dee et al., 2011), and to quantify the occurrence of cyclones and cutoffs during these spells. Hereby, we focus on the 20 longest wet spells (as per our definition of wet spells, see below) at each ERA-Interim grid point in Europe and address the following research questions:

- 1) How do the duration, accumulated precipitation, average precipitation rate and seasonality of the longest wet spells vary across Europe?
- 2) What synoptic storylines accompany these unusually long wet spells and how are cyclones and cutoffs involved in the generation of these wet spells?
- 3) How do the roles of cyclones and cutoffs in these synoptic storylines vary across Europe?

130 4) Where and how do the characteristics of cyclones and cutoffs during the longest wet spells differ significantly from climatology?

The structure of the paper is as follows. In Section 2 we introduce the data used in this study and elaborate on the statistical analyses performed here. The results of this study are presented in Section 3. We first discuss climatological characteristics of the longest wet spells in Europe (Section 3.1) and then present four case studies of unusually long wet spells at different locations, which each feature a distinct archetypal synoptic storyline (Section 3.2) and finally address research questions 3) and 4), by systematically analysing the occurrence of cyclones and PV cutoffs during the 20 longest spells at each grid point (Section 3.3). The paper ends with a discussion of these results (Section 4) as well as a summary and the conclusions of this study (Section 5).

## 2 Data and Methods

### 140 2.1 ERA-Interim

We use data from the European Centre for Medium-Range Weather Forecasts (ECMWF) ERA-Interim re-analysis from 1 January 1979 to 31 December 2018 for identifying wet spells and for the additional weather system investigations. ERA-Interim data has originally been produced with a T255 resolution and is interpolated here to a regular  $1^\circ$  latitude by  $1^\circ$  longitude grid. In ERA-Interim, precipitation is not an assimilated variable but rather stems from short-range model forecasts, with lead times of 6-18 hours, and is thus subject to model limitations and forecast errors. Pfahl and Wernli (2012) showed that indeed the intensity of sub-daily ERA-Interim precipitation extremes is often underestimated compared to satellite observation-based estimates, in particular in the tropics. However, the timing and location of intense precipitation is well represented in ERA-Interim in comparison with satellite observations (Pfahl and Wernli, 2012).

### 150 2.2 Definition of the longest wet spells

Here we focus on episodes with uninterrupted and significant, but not necessarily extreme precipitation. We therefore define a wet spell  $S$  as a sequence of consecutive days, each with at least 5 mm accumulated precipitation (which is the sum of large-scale and convective precipitation). At each grid point with coordinates  $(x, y)$  the 20 longest wet spells are considered, and this set of spells is referred to as  $\mathcal{S}_{20}(x, y)$ , where the  $n$ -th longest spell (i.e., an individual event, with a duration, starting date, accumulated precipitation value etc.) is denoted as  $S_n(x, y)$ . The coordinate specification  $(x, y)$  is omitted wherever possible without loss of clarity. Note that alternative definitions of wet spells, for example based on a different daily precipitation threshold or by allowing short gaps between precipitation episodes, would yield distinct sets of events for the top 20 longest wet spells per grid points. Thus, the identification of “the longest wet spells” is to some degree subjective, but the  $\mathcal{S}_{20}$  as defined here certainly classify as unusually long wet spells, which, due to the relatively high threshold for daily precipitation,

160 also have the potential to lead to societal impacts. Furthermore, we tested the sensitivity of our results to different sample sizes (top 5 and 10 longest wet spells) and found no qualitative differences, but for these smaller samples the results were statistically less robust.

### 2.3 Identification of cyclones and PV cutoffs

165 To identify cyclones the identification scheme of Wernli and Schwierz (2006) is employed, which first identifies local sea level pressure (SLP) minima and then finds for each local SLP minimum the outermost SLP contour that encloses only the respective minimum. This procedure yields a binary cyclone field with individual cyclone objects. The algorithm furthermore tracks these individual objects in time based on the location of the cyclone center (i.e., SLP minimum) [see Sprenger et al. (2017) for details of the tracking] and only cyclones with a lifetime of at least 24 hours are considered in this study.

170 PV cutoffs are identified and tracked according to the method of Portmann et al. (2021). This method first identifies PV cutoffs on individual isentropic surfaces between 275-360 K with 5 K intervals as isolated regions with PV values above 2 PVU following Wernli and Sprenger (2007). Then, PV cutoffs are defined as 3-dimensional objects that are vertically connected to the stratosphere. This largely removes high PV features of tropospheric origin that arise due to e.g. surface friction or diabatic heating. PV cutoffs are tracked in time based on Lagrangian air parcel trajectories and only cutoffs with a lifetime of at least  
 175 24 hours are retained [for details of the identification and tracking see Portmann et al. (2021)]. A key advantage of this approach compared to earlier PV cutoff identification and tracking routines is that it is independent of the selection of single vertical levels. For subsequent analyses we use the projection of the 3-dimensional cutoff objects onto the Earth's surface, which, as for cyclones, yields binary cutoff fields with individual cutoff objects.

### 2.4 Additional synoptic variables

180 In the synoptic discussion of example cases we furthermore consider the integrated vapor transport vector ( $\mathbf{IVT}$ ) and its magnitude (IVT, in units of  $\text{kg m}^{-1} \text{s}^{-1}$ ) which are defined as (e.g., Newell et al., 1992; de Vries, 2021)

$$\mathbf{IVT} = g^{-1} \int_{1050 \text{ hPa}}^{100 \text{ hPa}} q \mathbf{v} dp \quad (1)$$

and  $\text{IVT} = |\mathbf{IVT}|$ , respectively. Here,  $g$  is the gravitational acceleration,  $q$  is specific humidity and  $\mathbf{v}$  is the horizontal wind vector. Moreover, to quantify the effect of upper-level flow features (e.g., cutoffs) on vertical motion we examine the quasi-  
 185 geostrophic  $\omega$  forcing (in  $\text{hPa hour}^{-1}$ ), computed as in Graf et al. (2017) and Besson et al. (2021). Specifically, we use exactly the same data as Besson et al., (2021) and examine the quasi-geostrophic  $\omega$  at 500 hPa, forced from the atmospheric layers above 550 hPa and hereafter refer to this quantity simply as  $\text{QG}\omega$  [see Besson et al., (2021) and references therein for further details on the  $\text{QG}\omega$  data and its computation].

## 190 2.5 Quantifying the characteristics of cyclones and PV cutoffs during the $\mathcal{S}_{20}$

To quantify the characteristics of cyclones/cutoffs occurring during the  $\mathcal{S}_{20}(x, y)$  we consider for each grid point  $(x, y)$  cyclones and cutoffs whose masks overlapped with a circle of radius  $r$  around  $(x, y)$  during at least one 6-hourly time step of the  $\mathcal{S}_{20}(x, y)$ . For such cyclones and cutoffs we use the terminology “occurring at  $(x, y)$ ” hereafter for simplicity.

We compute four quantities for these cyclones and cutoffs:

- 195 1) The “cyclone/cutoff fraction”, which corresponds to the fraction of all  $\mathcal{S}_{20}$  time steps with cyclones/cutoffs occurring at  $(x, y)$ . This quantity is hereafter referred to as  $F_f(x, y)$ , whereby  $f$  corresponds to the respective feature (cyclones or cutoffs).
- 2) The “number of distinct cyclones/cutoffs” per spell,  $N_f(x, y)$ .
- 3) The “cyclone/cutoff period”,  $P_f(x, y)$ , which is the average duration between the arrival of distinct cyclones/cutoffs  
200 within the radius  $r$  around  $(x, y)$ , computed as the summed duration of the  $\mathcal{S}_{20}(x, y)$  divided by  $N_f(x, y)$ .
- 4) The “cyclone/cutoff residence time”,  $R_f(x, y)$ , which is the average duration during which distinct cyclones/cutoffs overlap with the radius  $r$  around  $(x, y)$ .

We tested values of  $r$  of 200 km, 400 km and 600 km and found little qualitative differences for any of these  $r$  values. For  
205 brevity, only the results for  $r = 400$  km are discussed in this manuscript, while those for  $r = 200$  km and  $r = 600$  km are shown in Figs. S6–9. Note that in the computation of these metrics we consider cyclones and cutoffs also if they overlap with the respective circle only during a short period, e.g., a single time step. Thus, in particular the residence time should be interpreted with such situations in mind. Furthermore, metrics  $P$  and  $R$  allow for distinguishing between recurrent features and stalling features in the following way: Recurrent cyclones or cutoffs manifest themselves with a short cyclone/cutoff period  
210 ( $P$ ), while long cyclone/cutoff residence times ( $R$ ) are expected for stalling cyclones and cutoffs.

To identify locally anomalous behaviour of cyclones and cutoffs during the respective  $\mathcal{S}_{20}$  we perform a Monte Carlo simulation in which we test the null-hypothesis that the four quantities and the occurrence of the  $\mathcal{S}_{20}$  are unrelated, and thus the observed  $F$ ,  $N$ ,  $P$  and  $R$  correspond to respective climatological values plus some random noise. The Monte Carlo  
215 approach is analogous to that in R othlisberger et al. (2016) and detailed here exemplarily for the cyclone fraction,  $F_{cyclone}(x, y)$ , but is applied in exactly the same fashion for all four metrics and both weather systems. First, the occurrence of the spells is randomized by shuffling the years of the  $\mathcal{S}_{20}(x, y)$ , while retaining the actual calendar days of these spells. Second, using these randomized spell dates, a randomized cyclone fraction  $F_{cyclone}^r(x, y)$  is computed exactly as the true cyclone fraction  $F_{cyclone}(x, y)$ . Third, this process is repeated 1000 times, and the resulting distribution of  $F_{cyclone}^r(x, y)$   
220 values is the distribution of  $F_{cyclone}(x, y)$  under the null-hypothesis that  $F_{cyclone}(x, y)$  and the occurrence  $\mathcal{S}_{20}(x, y)$  are

unrelated. Fourth, a two-sided p-value is then estimated at each grid point by comparing  $F_{cyclone}(x, y)$  with the distribution of the  $F_{cyclone}^r(x, y)$  values. Hereby, a p-value of zero is assigned if  $F_{cyclone}(x, y)$  lies outside the range of the  $F_{cyclone}^r(x, y)$  values. Fifth we reject the above null hypothesis for  $F_{cyclone}(x, y)$  values at a grid point wise significance level of 0.01. Note that the randomization through the shuffling of the years of the  $\mathcal{S}_{20}(x, y)$  conveniently circumvents issues arising from the spatially varying seasonality of the  $\mathcal{S}_{20}(x, y)$ .

Furthermore, in Section 3.3 we present anomalies of the four quantities for both weather systems. These are computed relative to climatological  $F$ ,  $N$ ,  $P$  and  $R$  derived as the mean over the respective 1000 randomized values (e.g., the climatological  $F_{cyclone}(x, y)$  is the mean of the 1000  $F_{cyclone}^r(x, y)$ ). Note that due to the spatially varying seasonality and duration of the  $\mathcal{S}_{20}$  the exact calendar days as well as the number of days contributing to the climatological values of  $F$ ,  $N$ ,  $P$  and  $R$  vary in space.

### 3 Results

#### 3.1 Climatological characteristics of the longest wet spells

We begin by discussing basic characteristics of the  $\mathcal{S}_{20}$  and their geographical variations. In many regions of Europe, the median duration of the  $\mathcal{S}_{20}$  is on the order of four to seven days (Fig. 1a). The  $\mathcal{S}_{20}$  are longest predominantly along the Atlantic coastal regions as well as in areas of elevated topography (see also Fig. S1f), and shortest over the Barents, Black and Baltic Seas. Median durations range from less than 4 days over parts of northern Scandinavia, Crimea, Germany, and Poland to more than two weeks in western Norway (Fig 1a). The overall longest European ERA-Interim wet spell occurred at 6°E/62°N, about 300 km north of Bergen, Norway (not shown). It started on 9 September 2018, lasted for 28 days, and finally ended on 6 October 2018. The accumulated precipitation during the  $\mathcal{S}_{20}$  co-varies with their median duration (Fig. 1a,b), and largest accumulations are found in Norway, north-western Iberia and Scotland (>200 mm in the median). The largest precipitation accumulation during a single wet spell again occurred in western Norway, at 6°E/61°N in January 1989 (not shown). The spell lasted for 24 days, and the accumulated ERA-Interim precipitation amounted to 471 mm. Note that at each grid point the variability in the duration and accumulated precipitation of the  $\mathcal{S}_{20}$  is large, and both the duration and accumulated precipitation can differ by more than a factor of two between the longest ( $\mathcal{S}_1$ ) and twentieth longest spell ( $\mathcal{S}_{20}$ ) at each grid point (Fig. S1a-d). This is an expected result as the  $\mathcal{S}_{20}$  constitute the top few percent of all wet spells with regard to duration at each grid point (Fig. S1e).

The average daily precipitation rate during the  $\mathcal{S}_{20}$  exceeds 5 mm day<sup>-1</sup> by definition (Fig. 1c), and its spatial variability differs somewhat from those of the median  $\mathcal{S}_{20}$  duration and accumulated precipitation. Largest daily precipitation rates during the  $\mathcal{S}_{20}$  are again found along the Iberian Atlantic coast and western Norway, with values in excess of 15 mm day<sup>-1</sup>, but also in

Mediterranean coastal regions. Average daily precipitation rates during the  $\mathcal{S}_{20}$  are locally anomalous, although not overly extreme. In most regions of Europe, they exceed the 95<sup>th</sup> percentile of the accumulated daily precipitation during all wet days (defined here as all days of the year with  $> 0.1$  mm accumulated precipitation) but are below the 97.5<sup>th</sup> percentile (Fig. 1c),  
255 implying that between 1 out of 20 and 1 out of 40 wet days feature comparable precipitation accumulations as the ones observed on average during the  $\mathcal{S}_{20}$ . This result underlines that the  $\mathcal{S}_{20}$  constitute a set of potentially high-impact precipitation episodes that is different from heavy precipitation events commonly identified based on very high ( $\geq 99^{\text{th}}$ ) percentiles of (sub)daily precipitation in previous studies (e.g., Pfahl and Wernli, 2012; Lenggenhager and Martius, 2019; Moore et al., 2021; de Vries, 2021).

260

The seasonality of the  $\mathcal{S}_{20}$  exhibits a clear spatial pattern. Over the North Atlantic and the eastern Mediterranean, most of the  $\mathcal{S}_{20}$  occur in winter (December–February, DJF), and likewise in southern Iberia and southwestern France. Over several coastal seas (the north-western Mediterranean, the North Sea, the Gulf of Bothnia and the Atlantic coastal seas near Iberia), the  $\mathcal{S}_{20}$  occur predominantly in fall (September–November, SON), while over continental eastern Europe (including Sweden, Finland,  
265 and western Russia), the vast majority of the  $\mathcal{S}_{20}$  happen during summer (June–August, JJA). At most grid points in central Europe, though, no season dominates the occurrence of the  $\mathcal{S}_{20}$ . In a spatially aggregated sense, spring (March–May, MAM) has by far the lowest number of spells as only 12.8% of the  $\mathcal{S}_{20}$  spells over land and ocean occurred in MAM, followed by 22.2% in JJA, 29.1% in SON and 35.9% in DJF. When only considering land grid points these contributions change markedly, with 17.6% of land  $\mathcal{S}_{20}$  spells occurring in MAM, 46.4% in JJA, 19.0% in SON and 17.0% in DJF. Next, we illustrate the  
270 palette of synoptic storylines of unusually long wet spells with four case studies of selected wet spells in different regions and seasons. These cases have been selected from a large number of cases we analysed, due to their archetypal and illustrative nature.

## 3.2 Case studies of selected unusually long wet spells

### 3.2.1 Long wet spell in western Russia – Quasi-stationary cutoff-cyclone couple

275 At  $37^{\circ}$  E/ $55^{\circ}$  N, close to Moscow, Russia, the longest wet spell [ $S_1$  ( $37^{\circ}$  E,  $55^{\circ}$  N)] occurred in July 2013 and lasted for 7 days (Fig. 2a). An examination of the large-scale flow pattern reveals a very persistent upper-level PV cutoff with a surface cyclone underneath during the entire spell (Fig. 3). At 12:00 UTC on 20 July, the first day of the spell, the cutoff C1 was located west of Moscow, reaching from  $75^{\circ}$  N southward to the Black Sea, with a weak surface cyclone L1 to its east (Fig. 3a). Precipitation occurred at the southeastern flank of the cutoff. Closer analysis shows that precipitation was primarily convective at  $37^{\circ}$  E/ $55^{\circ}$   
280 N (visible, e.g., from the diurnal pattern in precipitation at  $37^{\circ}$  E/ $55^{\circ}$  N, Fig. 2a), supported by QG $\omega$  ascent (Fig. S2a) and the decreased tropospheric static stability induced by the upper-level cutoff. Within the next four days, little changed in this synoptic configuration over western Russia, although from 21 July onwards, a second cutoff-cyclone pair (L2, C2) formed over the British Isles, resulting in a large-scale omega-type blocking pattern (Fig. 3b–e). The surface cyclone L1 weakened

considerably between 23 and 25 July, when its local sea level pressure minimum was no longer identified as a cyclone by the  
285 cyclone identification scheme (Fig. 3f). However, it re-appeared as an identified cyclone at 12:00 UTC on 26 July (labelled  
L1\* in Fig. 3g,h) and propagated eastward between 26 and 27 July, in tandem with the persisting cutoff C1 (Fig. 3f–h), which  
ultimately terminated the wet spell at 37° E/55° N on 27 July (Fig. 3h). Throughout the entire period, precipitation during  
daytime (06:00-18:00 UTC) strongly exceeded precipitation during nighttime (Fig. 2a), suggesting primarily diurnal  
convective precipitation throughout the entire period. However, upper-level forcing too contributed to precipitation at 37°  
290 E/55° N during the first days of the spell (Fig. S2). This case illustrates a first synoptic storyline of unusually long-lasting wet  
spells, in which a single quasi-stationary upper-level cutoff–surface cyclone couple repeatedly produces substantial  
precipitation in the same regions, by providing quasi-geostrophic forcing for ascent, destabilization of the troposphere  
underneath and thereby fosters diurnal convection (Hoskins et al., 1985; Portmann et al., 2018).

295 Extending the synoptic analysis to the 20 longest wet spells at the same grid point [ $\mathcal{S}_{20}(37^\circ \text{ E}, 55^\circ \text{ N})$ ] reveals considerable  
similarities in the large-scale flow across these events. The PV composite on 310 K for all  $\mathcal{S}_{20}(37^\circ \text{ E}, 55^\circ \text{ N})$  time steps shows  
a cyclonically breaking wave (e.g., Thorncroft et al., 1993) west of 37°E/55°N, which is associated with a weak negative SLP  
anomaly, a negative QG $\omega$  anomaly covering 37° E/55° N, and a northeastward directed *IVT* anomaly extending from the  
Black Sea towards 37° E/55° N (Fig. 7a). During 17 of the  $\mathcal{S}_{20}(37^\circ \text{ E}, 55^\circ \text{ N})$  at least one cutoff occurred (one spell featured  
300 even four distinct cutoffs), with an  $N_{cutoff}(37^\circ \text{ E}, 55^\circ \text{ N})$  of 1.65, and  $F_{cutoff}(37^\circ \text{ E}, 55^\circ \text{ N})$  equal to 0.38. Similarly, for  
cyclones we also find between zero and four distinct cyclones per spell, and  $N_{cyclone}(37^\circ \text{ E}, 55^\circ \text{ N})$  equals 1.9 and  
 $F_{cyclone}(37^\circ \text{ E}, 55^\circ \text{ N})$  is 0.64. Furthermore, the residence times of cyclones and cutoffs during the  $\mathcal{S}_{20}$  ( $R_{cyclone}$  and  $R_{cutoff}$ )  
at 37° E/55° N are 1.59 and 1.1 days, respectively.

### 305 **3.2.2 Long wet spell in central Norway – sequence of cyclones**

A contrasting synoptic storyline is evident for the longest wet spell at 14° E/66° N [ $\mathcal{S}_1(14^\circ \text{ E}, 66^\circ \text{ N})$ ], in Norway (Figs. 2b, 4  
and S3). This wet spell occurred between 24 January and 7 February 1989 and thus featured 15 continuous days with more  
than 5 mm accumulated ERA-Interim precipitation (Fig. 2b). At 12:00 UTC on 24 January 1989 (Fig. 4a), the large-scale flow  
over the North Atlantic was dominated by a broad trough, with a large surface cyclone L1 with two centers (local SLP minima)  
310 north of Iceland and east of the southern tip of Greenland. Over Europe, an amplified ridge R1 was present, but at its northern  
fringe a first pulse of onshore moisture transport (Fig. S3a) led to precipitation around 14° E/66° N (Fig. 4a), and started the  
wet spell there. Within the next two days (25–26 January), cyclone L1 moved eastwards, and three new SLP minima developed  
over the North Atlantic (contained in L2 and L3, Fig. 4b). The grid point at 14° E/66° N was located continuously in westerly  
flow associated with onshore moisture transport, and precipitation fell in association with two shortwave troughs propagating  
315 across Scandinavia in rapid succession (the latter of the two is visible in Fig. 4b as an upper-level PV filament between the  
British Isles and Scandinavia), which in addition provided upper-level forcing for ascent (Fig. 4b, S3b). Within the next five

days (Fig. 4b–e) cyclones L3–L5 formed over the western North Atlantic, rapidly propagated into the Norwegian Sea, and produced significant precipitation at 14° E/66° N. From 4 February onwards, the upper-level flow was remarkably zonal for three days, leading to continuous onshore moisture transport in particular south of 14° E/66° N, at the southern fringe of cyclones L6–L8, which passed to the north of the considered grid point (Fig. 4f,g). Finally, on 7 February, cyclone L9 developed south of Greenland and followed a more meridional track (Fig. 4g,h). L9 rapidly deepened until 9 February in association with upper-level cyclonic wave breaking (Fig. 4h). Rapid upper-level ridge-formation (R3) occurred downstream, presumably aided by diabatic processes occurring in L9’s strong warm conveyor belt (not shown). The formation of R3 interrupted the predominantly zonal flow and moisture transport over the eastern North Atlantic (Fig. 4h, S3h) and thereby terminated the wet spell. The few PV cutoffs were mostly small and filamentous and their influence on the wet spell thus seems less obvious.

In summary, the example of  $S_1(14^\circ \text{ E}, 66^\circ \text{ N})$  illustrates a second archetypal synoptic storyline for unusually long wet spells, in which a sequence of cyclones cross the same region in rapid succession. Hereby the moist North Atlantic airmasses impinging on the western Norwegian mountains conceivably generated orographic precipitation and thereby ensured the uninterrupted formation of precipitation, in particular during transition periods between individual cyclones. Moreover, the synoptic configuration of this spell is reminiscent of the North Pacific “zonal jet configuration” of Moore et al., (2021), within which numerous long-lasting heavy precipitation events in Northern California occurred. These authors emphasized the pivotal role of landfalling atmospheric rivers for long-lasting heavy precipitation events occurring in such a flow configuration. In this study we focus on cyclones and PV cutoffs and thus leave exploring the role of atmospheric rivers for the longest European wet spells to future work. Furthermore, it is noteworthy that a total of nine distinct cyclones identified by the Wernli and Schwerz (2006) algorithm were involved in the initiation, continuation and termination of  $S_1(14^\circ \text{ E}, 66^\circ \text{ N})$ , which is in stark contrast to the synoptic evolution of the previously discussed case near Moscow [ $S_1(37^\circ \text{ E}, 55^\circ \text{ N})$ ], in which only two objectively identified cyclones and a single cutoff appeared to be relevant.

We next examine the composite structure of the entire set of  $\mathcal{S}_{20}(14^\circ \text{ E}, 66^\circ \text{ N})$  (Fig. 7b). During these events, the composite large-scale upper-level flow was predominantly zonal over the North Atlantic (Fig. 7b), with a negative SLP anomaly north of 66° N, but a positive IVT anomaly (with peak values of roughly  $120 \text{ kg m}^{-1} \text{ s}^{-1}$ ) extending across the western North Atlantic and directed towards 14° E/66° N. Thirteen of the  $\mathcal{S}_{20}(14^\circ \text{ E}, 66^\circ \text{ N})$  featured five or more distinct cyclones, while the remaining spells featured between two and four distinct cyclones. For the  $\mathcal{S}_{20}(14^\circ \text{ E}, 66^\circ \text{ N})$  we find an  $N_{cyclone}(14^\circ \text{ E}, 66^\circ \text{ N})$  of 5.15, a  $F_{cyclone}(14^\circ \text{ E}, 66^\circ \text{ N})$  value of 0.51 and  $R_{cyclone}(14^\circ \text{ E}, 66^\circ \text{ N})$  equals 1.04 days, which underline the contrasting characteristics of cyclones affecting the  $\mathcal{S}_{20}$  at 14° E/66° N (numerous, recurrent, fast moving) and at 37° E/55° N (few and stationary), despite comparable cyclone fractions at these two grid points (0.51 vs. 0.64). Based on synoptic analyses of several

of the  $\mathcal{S}_{20}(14^\circ \text{ E}, 66^\circ \text{ N})$ , PV cutoffs seemed to be less relevant to the  $\mathcal{S}_{20}(14^\circ \text{ E}, 66^\circ \text{ N})$  than cyclones and are not discussed  
350 here.

### 3.2.3 Long wet spell in Tuscany – Recurrent wave breaking and cutoff replenishment

A third archetypal synoptic storyline occurred during the longest wet spell at  $12^\circ \text{ E}/43^\circ \text{ N}$ , in Tuscany, Italy [ $S_1(12^\circ \text{ E}, 43^\circ \text{ N})$ ; Figs. 2c, 5, and S4]. This 12-day wet spell occurred in association with a large cutoff-complex over the Mediterranean that  
355 first formed after an anticyclonic wave breaking event over the North Atlantic/Europe (S1 in Fig. 5a) and was then replenished multiple times by a sequence of further wave breaking events occurring in a similar location (Fig. 5a-e). At 12:00 UTC on 1 May 2018 (Fig. 5a), the PV streamer S1 was located over western Europe and substantial precipitation fell to its east, where QG ascent and enhanced northeastward moisture transport took place. At its southern fringe, cyclone L1 started tracking north-eastward. At the same time, the incipient streamer S2 was already apparent west of the UK (Fig 5a). Within the next two days  
360 streamer S1 formed cutoff C1, while S2 developed into a next elongated PV-filament that, on 320 K, reached all the way to Morocco (Fig. 5b). The cutoff C1 and cyclone L1 aligned vertically in an equivalent barotropic manner, and precipitation fell underneath this cutoff-cyclone couple (Fig 5b). Within the next two days, parts of the high-PV air of streamer S2 were absorbed into cutoff C1, which was thereby substantially enlarged (Fig. 5c). At the same time, a strong anticyclone formed over northern Europe and a next wave breaking event (S3) occurred at its downstream flank on 5 and 6 May (Fig. 5c,d). The resulting PV  
365 streamer S3 also produced two small cutoffs (the more southerly one is labelled C2 in Fig. 5d), which tracked westward (Fig. 5d,e) and ultimately merged with C1 on 9 May (Fig. 5f). Between 5 and 9 May, a Rex-type blocking pattern (Rex, 1950) was present over Europe and the Mediterranean. The cutoff-complex C1 hereby acted as the positive PV anomaly on the equatorward side of the blocking pattern, covered large parts of the Mediterranean, destabilized the air underneath and led to (primarily daytime, e.g., Fig. 2c) precipitation from Iberia all the way to Turkey (Figs. 5c–f). Thereby, both IVT and  $QG\omega$   
370 were small around  $12^\circ \text{ E}/43^\circ \text{ N}$  between 9 and 12 May (Fig. S4e–g), as the cutoff-complex C1 weakened. Nevertheless, still sufficient (convective) precipitation fell at  $12^\circ \text{ E}/43^\circ \text{ N}$  to prolong the wet spell there for another three days, until it finally ended on 12 May. By 12:00 UTC 13 May, C1 had decayed entirely, although a next cutoff (C3) already approached from the west. Interestingly, only one surface cyclone (L1) was involved in the 12-day spell  $S_1(12^\circ \text{ E}, 43^\circ \text{ N})$ , and was only present during roughly the first half of the spell. Thus, the destabilizing effect of the cutoff-complex C1, its formation, quasi-  
375 stationarity and replenishment due to recurrent wave breaking events, are key to this spell.

The 12-day spell  $S_1(12^\circ \text{ E}, 43^\circ \text{ N})$  is perhaps surprising in that it featured only one cyclone, despite its relatively long duration. However, a small number of cyclones is a common characteristic of the  $\mathcal{S}_{20}(12^\circ \text{ E}, 43^\circ \text{ N})$ , as 11 of them featured two or less cyclones. The synoptic analysis of this case suggests that the cutoff-complex C1 can be regarded as an individual, long-lived  
380 system, but two cutoffs that merged with the cutoff complex (visible e.g., in Fig. 5d) increased the cutoff count of this spell to three [according to the Portmann et al (2021) cutoff data]. The composite fields of 320 K PV, SLP, *IVT* and  $QG\omega$  during the  $\mathcal{S}_{20}(12^\circ \text{ E}, 43^\circ \text{ N})$  are consistent with the synoptic evolution of  $S_1(12^\circ \text{ E}, 43^\circ \text{ N})$  (Fig. 7c), with an amplified trough upstream

of 12° E/43° N that is associated with anomalous *IVT* on its southern and eastern fringes, negative  $QG\omega$  centred on 12° E/43° N and a negative SLP anomaly across the western Mediterranean. However, the  $S_{20}(12^\circ \text{ E}, 43^\circ \text{ N})$  also contain at least one  
385 spell with a strongly differing synoptic storyline: Contrary to  $S_1(12^\circ \text{ E}, 43^\circ \text{ N})$ , the spell  $S_5(12^\circ \text{ E}, 43^\circ \text{ N})$  occurred in winter and featured five distinct cyclones and five distinct cutoffs that were steered towards 12° E/43° N by a southward displaced jet over the eastern North Atlantic (not shown).

### 3.2.4 Long wet spell in eastern Europe – Intermittent periods of diurnal convection and recurrent cutoff formation

390 A fourth synoptic storyline is illustrated based on the longest wet spell at 25° E/48° N, in the Carpathian Mountains at the border between Romania and Ukraine (Figs. 2d, 6, and S5). This wet spell lasted for an impressive 17 days, from 19 May to 4 June 1988 and featured several days with substantial precipitation without the presence of any cutoff or cyclone near 25° E/48° N. During intermitted periods of this spell a total of three cutoffs appeared in the vicinity of 25° E/48° N, which, however, did not induce substantial  $QG\omega$ , but conceivably contributed to the persistence of the spell by reducing the static stability  
395 underneath. At 12:00 UTC on 20 May 1988 a breaking wave (S1 in Fig. 6) was present over western Europe, while a surface anticyclone was located over western Russia. In-between, an area of weak SLP gradients extended across much of the Balkans and eastern Europe, and precipitation occurred over widespread areas in this region (Fig. 6a), without any considerable  $QG\omega$  or *IVT* (Fig. S5a). At 25° E/48° N the ERA-Interim precipitation on the first two days of the spell (19 and 20 May) fell exclusively between 06 and 18 UTC (Fig. 2d), consistent with primarily convective precipitation. Over the course of the next  
400 four days, a weak positive PV feature (S1) propagated slowly eastward (not shown) and eventually broke up into several remnants by 12:00 UTC on 24 May, including a cutoff C1 which covered 25° E/48° N at that time step (Fig. 6b). Between 21 May and 24 May, precipitation at 25° E/48° N exhibited less of a diurnal cycle (Fig. 2d), likely due to the influence of the upper-level PV feature which continuously destabilized the troposphere and provided quasi-geostrophic forcing for ascent (not shown). From 24 to 26 May the cutoff C1 remained in the vicinity of 25° E/48° N, but gradually weakened until its dissipation  
405 on 27 May (Fig. 6b–d). At 12:00 UTC on 27 May a flow situation very much reminiscent of that on 12:00 UTC 20 May had established, with a PV streamer S2 approaching 25° E/48° N, and widespread precipitation around 25° E/48° N, but again without the apparent influence of a cyclone or cutoff (Fig. 6d, S5d). The streamer S2 again formed a cutoff (C2), which approached 25° E/48° N by 12:00 UTC on 29 May (Fig. 6e) and dissipated thereafter until 12:00 UTC on 30 May (not shown). It is noteworthy that during the first 13 days of the spell (19–31 May 1988) no surface cyclone is apparent in the immediate  
410 vicinity of 25° E/48° N. The large-scale flow situation changed considerably between 29 May and 1 June (Fig. 6e,f): a next PV streamer (S3) approached 25° E/48° N, induced upper-level forcing for ascent as well as a pulse of poleward moisture transport on its downstream side (Fig. S5f), and a surface cyclone L1 developed to its east (Fig. 6f). The cyclone L1 deepened from 12:00 UTC on 1 July to 18:00 UTC on 2 June (Fig. 6g), and passed over 25° E/48° N, which led to the largest daily precipitation accumulations during the entire spell (Fig. 2d). By 12:00 UTC on 4 June, the streamer S3 had formed yet another  
415 cutoff (C3 in Fig. 6h), which slowly propagated eastward together with L1, and the spell finally ended on 5 June.

The synoptic storyline of this spell is interesting in two regards: Firstly, during its first part precipitation fell due to diurnal convection, and the influence of surface cyclones or PV cutoffs appeared to be modest at best. Secondly, during the remainder of the spell it involved multiple cutoffs and PV streamers. Based on this case study, the intermittent occurrence of days with daytime convection in absence of direct upper-level forcing, alternated by days with recurrent wave breaking and cutoff formation thus emerges as a further archetypal storyline for unusually long wet spells. It should be noted that a similar synoptic storyline has recently been reported for a multi-week period of recurrent convective events in central Europe (Mohr et al., 2020).

The composite fields of 320 K PV, SLP, IVT and  $QG\omega$  for all  $\mathcal{S}_{20}(25^\circ \text{ E}, 48^\circ \text{ N})$  reveal a similar pattern as e.g., in Fig. 6a,c,d,e,h, and underline the limited relevance of the large-scale forcing for the  $\mathcal{S}_{20}(25^\circ \text{ E}, 48^\circ \text{ N})$ : Contrary to the other three case study locations SLP and IVT anomalies are remarkably weak around  $25^\circ \text{ E}/48^\circ \text{ N}$ , and only a weak upper-level PV feature (discernible only from the composite 1 PVU contour) is associated with modest negative  $QG\omega$  anomalies (just below  $-0.5 \text{ hPa hour}^{-1}$ ). The cyclone fraction,  $F_{cyclone}$ , is 0.21, which further underlines that the role of cyclones is much more subtle for the  $\mathcal{S}_{20}$  at  $25^\circ \text{ E}/48^\circ \text{ N}$  than, e.g., at  $14^\circ \text{ E}/66^\circ \text{ N}$  (Norway case, Figs. 2b, 4, 7b), where  $F_{cyclone}$  is 0.51. As for  $12^\circ \text{ E}/43^\circ \text{ N}$  (Tuscany) the variability in the cyclone and cutoff characteristics across the  $\mathcal{S}_{20}$  is large, with between zero and five (one and six) distinct cyclones (cutoffs) during individual  $\mathcal{S}_{20}(25^\circ \text{ E}, 48^\circ \text{ N})$  spells.

### 3.3 A systematic analysis of cyclone and PV cutoff characteristics during the $\mathcal{S}_{20}$

We next examine the occurrences of cyclones and cutoffs during the  $\mathcal{S}_{20}$  across Europe more systematically to elucidate geographical differences in their role for generating unusually long-lasting wet spells (the left columns in Figs. 8 and 9). Furthermore, we assess whether or not the behaviour of cyclones and cutoffs during the  $\mathcal{S}_{20}$  is locally anomalous (right columns in Figs. 8 and 9). We begin by discussing the cyclone fractions,  $F_{cyclone}$ , and their anomalies (Fig. 8a,b). Cyclones occur during more than 60% of the  $\mathcal{S}_{20}$  time steps over vast parts of the North Atlantic, Scandinavia as well as the northern and eastern Mediterranean (Fig. 8a). Moreover,  $F_{cyclone}$  is generally larger over the ocean than over land, with exceptions over large parts of Scandinavia and the UK. In the Balkans, the Caucasus and parts of the Alps, however, cyclones occur during only roughly 10-30% of the  $\mathcal{S}_{20}$  time steps, suggesting that they do not play a major role in the longest wet spells there. The  $F_{cyclone}$  anomalies (Fig. 8b) are positive and statistically significant almost everywhere, with largest anomalies in the Mediterranean and the subtropical North Atlantic. Insignificant  $F_{cyclone}$  anomalies are found in the aforementioned areas of particularly low  $F_{cyclone}$  (which is consistent with the Balkan case study, Section 3.2.4), and, interestingly, also along the west coast of Norway.

The Norway case study (Section 3.2.2) revealed a large number of cyclones contributing to the longest spell at  $14^\circ \text{ E}/66^\circ \text{ N}$ , suggesting that serial clustering of extratropical cyclones (Pinto et al., 2014; Priestley et al., 2017a; Dacre and Pinto, 2020)

might be crucial for the occurrence of unusually long wet spells in this region. Figure 8e now reveals that in this region the  
450 cyclone period,  $P_{cyclone}$ , is indeed shorter than anywhere else in Europe, with values between 1.5 and two days. Also,  
anomalously large  $N_{cyclone}$  and anomalously short  $P_{cyclone}$  at some grid points around  $14^\circ$  E/ $66^\circ$  N somewhat support the  
hypothesis of anomalous serial cyclone clustering as cause of long wet spells there. However, for numerous grid points along  
the west coast of Norway, none of the four quantities' anomalies are statistically significant, a result that will be further  
discussed in Section 4. A much clearer indication for anomalous serial cyclone clustering as a cause of the longest wet spells  
455 is found e.g., across central Europe, in southwestern Scandinavia and parts of the United Kingdom (UK), where  $F_{cyclone}$  is  
increased due to significantly more distinct cyclones (positive  $N_{cyclone}$  anomalies) occurring at higher rate (reduced  $P_{cyclone}$ ),  
with  $R_{cyclone}$  not significantly different from climatology.

A further region with particularly noteworthy cyclone characteristics (and their anomalies) during the  $\mathcal{S}_{20}$  is found in the seas  
460 south of Italy. This region features some of the largest cyclone residence times ( $R_{cyclone}$  in excess of two days, Fig. 8g) and  
the largest significant anomalies in  $R_{cyclone}$  (up to 1 day, Fig. 8h) anywhere in the study region. Notably in the seas south of  
Italy,  $N_{cyclone}$  and  $P_{cyclone}$  do not differ significantly from climatology (Fig. 8d,f) despite  $F_{cyclone}$  anomalies of up to 40%,  
which corresponds to roughly a doubling of  $F_{cyclone}$  during the  $\mathcal{S}_{20}$  compared to climatology (compare Figs. 8a and b). These  
large  $F_{cyclone}$  anomalies thus come about primarily due to increased  $R_{cyclone}$ , i.e., anomalously persistent, i.e., slower moving  
465 and/or longer-lived cyclones compared to climatology.

Next, we discuss the four quantities and their anomalies for cutoffs (Fig. 9) and contrast them with results for cyclones (Fig.  
8). The cutoff fraction,  $F_{cutoff}$ , as well as the number of distinct cutoffs per  $\mathcal{S}_{20}$  spell,  $N_{cutoff}$ , are considerably smaller than  
 $F_{cyclone}$  and  $N_{cyclone}$  (compare Fig. 9a,c with Fig. 8a,c). Much fewer of the  $F_{cutoff}$  and  $N_{cutoff}$  anomalies are statistically  
470 significant compared to  $F_{cyclone}$  and  $N_{cyclone}$  anomalies, but wherever  $F_{cutoff}$  and  $N_{cutoff}$  anomalies are significant they are  
also positive, showing that enhanced PV cutoff fractions and numbers are associated with the wet spells (Fig. 9a,c). Largest  
values of  $F_{cutoff}$  are found in the western Mediterranean, where they exceed the respective climatological values by roughly  
a factor of two (Fig. 9a,b). The cutoff period  $P_{cutoff}$  reveals considerable geographical variations (Fig 9e), with shortest cutoff  
periods around 2 days in the Norwegian Sea, but as for  $N_{cutoff}$ , the  $P_{cutoff}$  anomalies are significant only in few and separate  
475 regions. The most striking result for cutoffs, though, is the significantly increased residence time  $R_{cutoff}$  in the Mediterranean.  
There,  $R_{cutoff}$  values in excess of two days are observed, which is more than 1 day more than the climatological value. Thus,  
the anomalously large  $F_{cutoff}$  during the  $\mathcal{S}_{20}$  in this region predominantly results from increased residence times of cutoffs,  
i.e., persistent cutoffs that are either slower-moving, longer-lived or both. A similar behaviour of cutoffs during the  $\mathcal{S}_{20}$  is  
found in the southwestern corner of our study domain, over the subtropical North Atlantic.

480

Over land, comparatively long absolute  $R_{cutoff}$  values (up to 1.75 days) are found in the Balkans and in north-eastern Europe (Figs. 9g), suggesting that in these regions, the cutoffs involved in the  $\mathcal{S}_{20}$  are more persistent than, e.g., those involved in the  $\mathcal{S}_{20}$  along the Norwegian coast or in western Europe (note, however, that the  $R_{cutoff}$  anomalies are insignificant at most grid points in these regions). Nevertheless, throughout Europe's land area  $F_{cutoff}$  is below 50% almost everywhere (Fig. 9a),  
485 indicating that during at least half of the total  $\mathcal{S}_{20}$  time no cutoff is present within a 400 km radius.

In summary, this section reveals geographically varying and, in some regions, locally anomalous behaviour of cyclones and cutoffs during the  $\mathcal{S}_{20}$ .  $F_{cyclone}$  is anomalously large during the  $\mathcal{S}_{20}$  almost everywhere, however, the causes of these positive cyclone frequency anomalies differ in space. Increased numbers of cyclones during the  $\mathcal{S}_{20}$  explain the positive  $F_{cyclone}$   
490 values along the north-western Atlantic coast as well as in central Europe, while over the Mediterranean anomalously large residence times of cyclones are the primary reason for positive  $F_{cyclone}$  anomalies. The Mediterranean is also the region where  $F_{cutoff}$  deviates most from its climatological value, which is caused by anomalously persistent cutoffs during the  $\mathcal{S}_{20}$ . Elsewhere, the characteristics of cutoffs during the  $\mathcal{S}_{20}$  vary in space, but rarely differ significantly from climatological cutoff characteristics.

#### 495 **4 Discussion**

The synoptic storylines for unusually long wet spells presented in Section 3.2 feature individual stalling cyclones and cutoffs as well as multiple recurrent such weather systems [as anticipated by Moore et al., (2021)], although some storylines are more complex and also involve daytime convection over complex topography without apparent upper-level forcing. The four case studies were selected due to their archetypal nature, however, manual analyses of a large number of further long wet spells  
500 revealed numerous storylines that combined various features of the four archetypal storylines (e.g., multiple stationary cutoff-cyclone couples or multiple recurrent cyclones preceding a particularly stationary cutoff, etc.). Furthermore, this manual analysis revealed that distinct wet spells at a single location often do not follow the same synoptic storyline. This diversity raises the question whether or not these synoptic storylines at all stratify according to geographical regions, which motivated our climatological analysis of cutoff and cyclone characteristics during the  $\mathcal{S}_{20}$  presented in Figs. 8 and 9.

505

The two columns in Figs. 8 and 9 address distinct research questions. The left column assesses how cyclone and cutoff characteristics during the  $\mathcal{S}_{20}$  vary in space and thus addresses research question 3) in the Introduction. This information is valuable, since the general relevance of cyclones and cutoffs for precipitation is well established (e.g., Hawcroft et al., 2012; Portmann et al., 2020) and thus, e.g., spatial variations in  $F_{cyclone}$  point to a spatially varying relevance of cyclones for the  
510  $\mathcal{S}_{20}$ . Nevertheless, the spatial variations in these cyclone and cutoff characteristics during the  $\mathcal{S}_{20}$  are governed in part by climatological characteristics of cyclones and cutoffs. Therefore, the right column in Figs. 8 and 9 also compares the

cyclone/cutoff characteristics during the  $\mathcal{S}_{20}$  to climatological values, in order to identify anomalous weather system characteristics during the  $\mathcal{S}_{20}$  (and thus address research question 4).

515 The left columns in Figs. 8 and 9 reveal that the relevance of cyclones and cutoffs for the  $\mathcal{S}_{20}$  indeed varies greatly across space. For example, the range of  $F_{cyclone}$  values with lowest values below 0.2 and largest values above 0.9 implies that in some regions, cyclones are present during almost the entire period of the  $\mathcal{S}_{20}$ , e.g., in Scandinavia, the UK, and Mediterranean, while cyclones appear to be largely irrelevant to the  $\mathcal{S}_{20}$  in other regions such as the Balkans. Furthermore,  $F_{cutoff}$  varies from around 0.2 (e.g., over Finland) to 0.7 (over the western Mediterranean), indicating that a major fraction of the total  $\mathcal{S}_{20}$  duration  
520 occurs without a cutoff within a 400 km radius, even in the regions with the largest  $F_{cutoff}$ .

The right columns in Figs. 8 and 9 show single-signed or insignificant anomalies of  $F$ ,  $N$ ,  $P$  and  $R$  almost throughout the study region for both weather systems, with positive anomalies in  $F$ ,  $N$  and  $R$ , and negative anomalies in  $P$ . Thus, wherever the  $F$ ,  $N$ ,  $P$  and  $R$  anomalies are significant, the respective weather systems are more prevalent (positive  $F$  anomalies), occur in larger  
525 number (positive  $N$  anomalies), at a higher rate (negative  $P$  anomalies) and tend to be more persistent (positive  $R$  anomalies) during the  $\mathcal{S}_{20}$  than in climatology. However, not all grid points feature significant anomalies, in particular not for cutoffs. The lack of statistically significant anomalies in any of the four quantities may result from three causes: (a) at some grid points, there is simply no preferred synoptic storyline of the  $\mathcal{S}_{20}$  with a clear signature in the four cyclone and cutoff characteristics,  $F$ ,  $N$ ,  $P$  and  $R$ , which may be the case for example in regions where the  $\mathcal{S}_{20}$  occur in different seasons. (b) The sample size  
530 (20) is relatively small for a statistical hypothesis test, consequently our Monte Carlo test has only limited power to detect significant departures from climatology (e.g., Wilks, 2011). (c) In certain regions, e.g., the west coast of Norway, the climatological precipitation variability is itself characterized by long wet spells (Zolina et al., 2013). In such regions, unusually long wet spells do not need to be associated with anomalous cyclone and cutoff characteristics, but rather with close to climatological characteristics over a prolonged period.

535 Nevertheless, for cyclones the anomalies of  $F$ ,  $N$  and  $P$  are significant in vast areas of the study region. Comparing the right columns in Figs. 8 and 9 we find overall weaker and much fewer significant anomalies in  $F$ ,  $N$ ,  $P$  and  $R$  for cutoffs than for cyclones, which suggests a generally weaker link between anomalous cutoff characteristics and the occurrence of the  $\mathcal{S}_{20}$  than for cyclones. In part this could be a consequence of the cutoff definition of Portmann et al., (2021), who defined cutoffs as  
540 three dimensional objects, which can persist as vertically shallow objects on relatively high isentropes, where their influence on lower and mid-tropospheric static stability as well as ascent is limited (see Portmann et al., 2018 for an example of such a case).

In the Mediterranean, however,  $F_{cutoff}$  and  $R_{cutoff}$  anomalies are of similar magnitude as the  $F_{cyclone}$  and  $R_{cyclone}$  anomalies, and underline the importance of persistent cutoffs and cyclones for the  $\mathcal{S}_{20}$  there. This result is consistent with several previous studies, in particular Doswell et al., (1998), who documented a 7-day heavy precipitation event in Valencia, Spain, and Portmann, (2020) who showed that the Mediterranean is the region where cutoffs contribute the most to annual precipitation anywhere on the globe. Furthermore, de Vries (2021) identified the Mediterranean as a region where the odds of extreme precipitation events are significantly increased when upper-level high-PV features are present. A novel finding of this study is that cutoffs can be key dynamical precursors to even much longer precipitation episodes, in particular if such cutoffs are replenished by multiple wave breaking events (Section 3.2.3) or when multiple recurrent cutoffs are involved (Section 3.2.4). In either case, the longevity of the wet spells appears to be linked to recurrent synoptic-scale Rossby wave dynamics (the formation, amplification and breaking of upper-level troughs). Subsequent research could therefore investigate whether or not these spells have statistically significant Rossby wave precursors, possibly in the form of recurrent Rossby wave packets (Ali et al., 2021; Röthlisberger et al., 2019).

The finding that long wet spells along the west coast of Europe associated with multiple recurrent cyclones (e.g., Section 3.2.2) is not surprising, in particular given the clear evidence for serial cyclone clustering in the eastern North Atlantic (Mailier et al., 2006; Pinto et al., 2014; Priestley et al., 2017a; Dacre and Pinto, 2020). Indeed, the Norway case study (Section 3.2.2) features several aspects of the archetypal pathway to cyclone clustering outlined in Priestley et al., (2017a), with recurrent anticyclonic wave breaking over the North Atlantic on the equatorward side of the jet (e.g., Fig. 4b,c), a zonally extended and northward displaced jet (not shown) that leads to strong and persistent westerly flow impinging on Scandinavia and steers cyclones towards northern Scandinavia (Fig. 4). Furthermore, as in Priestley et al., (2017a), the cyclone clustering period is terminated when a cyclonic wave breaking event displaces the North Atlantic jet southward (Fig. 4h). Perhaps more surprising is the lack of significantly positive cyclone frequency anomalies along the northern Norwegian coast (Fig. 8b), which likely points to the relevance of a stagnant westerly moist air flow that supports orographic precipitation during the  $\mathcal{S}_{20}$  there. Furthermore, the insignificant anomalies of  $N_{cyclone}$  and  $P_{cyclone}$  in Norway (close to 14° E/66° N) are consistent with our explanation (c) above, i.e., serial clustering of cyclones is a climatological characteristic of cyclones in the eastern North Atlantic (Mailier et al., 2006), thus, it is certainly relevant to the generation of long wet spells there, but not an anomalous behaviour of cyclones there.

The results of and conclusions from this study are limited in a number of ways. Firstly, we use precipitation from ERA-Interim as opposed to observed precipitation (remotely sensed or in-situ measured). Consequently, the identification of the  $\mathcal{S}_{20}$  is affected by precipitation biases in ERA-Interim (see also Section 2.1). However, using ERA-Interim precipitation for the spell identification is convenient as it is spatially and temporally complete and, furthermore, ensures that the precipitation is physically consistent with the synoptic-scale dynamics accompanying the long wet spells studied here. Secondly, the criteria for defining “wet spells” are to a certain degree subjective and, consequently, our definition of wet spells as consecutive days

with at least 5 mm daily accumulated ERA-Interim precipitation strongly affects which events ultimately end up in the  $\mathcal{S}_{20}$ . Nevertheless, choosing a higher precipitation threshold than previous studies (e.g., Ali et al., 2021; Zolina et al., 2010, 2013) ensures that our  $\mathcal{S}_{20}$  are unusually long-lasting periods of sustained relatively intense precipitation, and thus potentially high-impact events. Thirdly, our analyses focus primarily on only two types of synoptic systems, cutoffs and cyclones. The choice of these two systems is motivated by previous studies, who documented the particular relevance of these two types for long-lasting heavy precipitation episodes (Doswell et al., 1998; Raveh-Rubin and Wernli, 2015; Moore et al., 2021), and our case studies further underline this pivotal role of cutoffs and cyclones for long wet spells. Subsequent research should nevertheless explore to what extent other weather systems such as stagnating atmospheric rivers (e.g., Moore et al., 2021) or blocking (e.g., Mohr et al., 2020) foster the occurrence of unusually long wet spells in their vicinity.

## 5 Summary and conclusions

This study investigates the role of cyclones and PV cutoffs for the formation of unusually long wet spells in Europe, which are identified at each ERA-Interim grid point as the 20 longest uninterrupted periods with at least 5 mm daily accumulated ERA-Interim precipitation ( $\mathcal{S}_{20}$ ). The  $\mathcal{S}_{20}$  are longest along the Norwegian coast and northern Scotland, where the median duration of the  $\mathcal{S}_{20}$  reaches up to two weeks. The  $\mathcal{S}_{20}$  are shortest e.g., in Poland and north-eastern Scandinavia, where their median duration is only 3-5 days. There is a clear seasonality associated with the occurrence of the  $\mathcal{S}_{20}$ : over eastern continental Europe they occur predominantly in summer, while over the North Atlantic most of the  $\mathcal{S}_{20}$  occur in winter, and the majority of the  $\mathcal{S}_{20}$  along European coastal seas and the Mediterranean occur in winter or fall. In central and western Europe, no season clearly dominates.

Four case studies reveal distinct synoptic storylines of selected long wet spells, that each involve cyclones and/or PV cutoffs in distinct ways. The longest wet spell in Moscow occurred in association with just one cutoff-cyclone couple that formed from a single wave breaking event, subsequently stalled over western Russia and thus produced >5 mm/day precipitation at this grid point for seven consecutive days. An even longer spell (12 days) associated with a single cutoff-complex occurred in Tuscany, Italy. Initially, this cutoff-complex also formed from a wave breaking event but, in contrast to the Moscow case, was then replenished multiple times by multiple further wave breaking events over the North Atlantic and Europe. The Tuscany case thus illustrates recurrent wave breaking and subsequent cutoff replenishment as a further, hitherto not documented synoptic storyline for unusually long wet spells. In contrast, a substantial body of literature documents the tendency for North Atlantic extratropical cyclones to serially cluster in the North Atlantic region (Dacre and Pinto, 2020 and references therein). Here we document such behaviour of extratropical cyclones during a 15-day wet spell in Norway, which also involved orographic precipitation in westerly onshore flow. Finally, a 17-day wet spell in the Balkans reveals the importance of diurnal convection for this long summer-time wet spell over continental Europe, and also featured recurrent cutoffs that occur intermittently with periods of diurnal convection in absence of evident upper-level forcing.

To compare cyclone and cutoff characteristics during the  $\mathcal{S}_{20}$  in space as well as to climatological cyclone/cutoff characteristics we compute four quantities for both types of weather features and for each grid point  $(x, y)$ , which each consider cyclones and cutoffs that overlap with a radius of 400 km around  $(x, y)$  during the  $\mathcal{S}_{20}(x, y)$ : The cyclone/cutoff fraction  $F$ , the number of distinct cyclones/cutoffs per spell,  $N$ , the cyclone/cutoff period,  $P$ , and the cyclone/cutoff residence time  $R$ .

615 This analysis reveals regionally strongly varying roles of cutoffs and cyclones for the  $\mathcal{S}_{20}$ . For instance, the absolute values of  $F_{cyclone}$  vary from less than 0.2 in the Balkans (i.e., cyclones almost never present during the  $\mathcal{S}_{20}$ ) to more than 0.8 over the North Atlantic (i.e., the  $\mathcal{S}_{20}$  occur under quasi-continuous influence of cyclones). For both weather features, the anomalies of  $F$ ,  $N$ ,  $P$  and  $R$  are single-signed (or statistically not significant) throughout Europe and imply that, during the  $\mathcal{S}_{20}$ , cyclones and cutoffs are more prevalent (positive  $F$  anomalies), occur in larger number (positive  $N$  anomalies), at a higher rate (negative  
620  $P$  anomalies) and are more persistent (positive  $R$  anomalies) compared to climatology. Hereby larger anomalies of these quantities, with higher statistical significance, are found for cyclones than for cutoffs in most regions, which suggests a tighter association between anomalous weather system characteristics and long wet spells for cyclones than for cutoffs. An exception to this rule is found in the western Mediterranean, where cutoffs have strongly and statistically significantly increased residence times during the  $\mathcal{S}_{20}$ .

625

We conclude that the synoptic storylines accompanying unusually long wet spells are highly diverse across Europe. Cutoffs and cyclones were involved in all cases we analyzed, either as individual and unusually persistent systems or in a recurring manner. A novel finding of this study is that recurrent Rossby wave breaking may act as an indirect precursor to unusually long wet spells, by replenishing an existing cutoff which subsequently fosters the occurrence of an unusually long wet spell.

630 Subsequent research should therefore investigate how unusual recurrence and unusual longevity of synoptic systems comes about and how the two are intertwined. Furthermore, given the potential impacts of unusually long wet spells as well as their potential changes in a warming climate (e.g., Pfliegerer et al., 2019), it is important to investigate whether or not climate models are able to realistically reproduce the synoptic characteristics of such events, in order to assess the reliability of projected changes in wet spell characteristics. This study documents for the first time the palette of synoptic storylines  
635 accompanying unusually long wet spells across Europe, and thus forms a basis for such climate model evaluations.

*Data availability.* ERA-Interim data can be downloaded from the ECMWF webpage (<https://apps.ecmwf.int/datasets/data/interim-full-daily/levtype=sfc/>).

640 *Author contributions.* BS and MR performed the analyses and BS produced earlier versions of the Figures 1, 3, 4 and 7–9 as part of her MSc Thesis research. MR conceived the study, produced the final figures and wrote the manuscript, RP and AJdV discussed intermediate results, and commented earlier versions of this manuscript.

*Competing interests.* The authors declare no conflict of interest.

645

*Acknowledgements.* All authors would like to thank Heini Wernli (ETH Zürich) for helpful discussions, feedback on an earlier version of this manuscript and his general support for this study. Moreover, we are indebted to Michael Sprenger (ETH Zürich) for providing the QG $\omega$  data. MR acknowledges funding of the INTEXseas project from the European Research Council (ERC) under the European Union's Horizon 2020 research and innovation programme (grant agreement No 787652), and AJdV funding of the Swiss National Science Foundation (grant no. 177996), and RP funding from the ETH Zurich (grant no. ETH-0716-2).

795

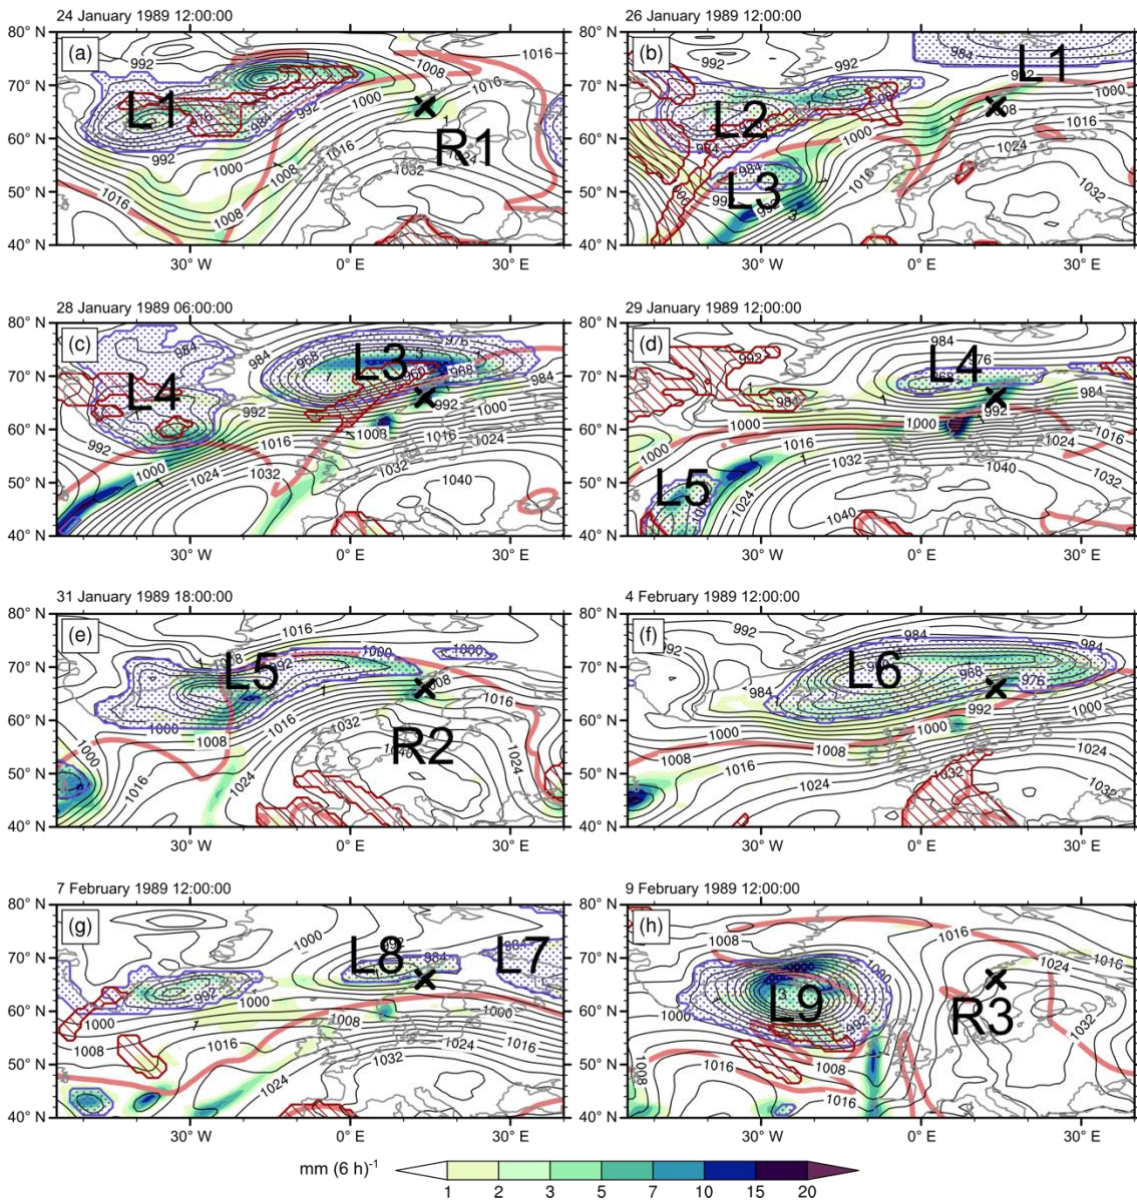

800 **Figure 1.** Characteristics of the 20 longest wet spells at every ERA-Interim grid point ( $\mathcal{S}_{20}$ ). (a) median duration, (b) median accumulated precipitation, and (c) average daily precipitation rate; (d) the season in which the largest fraction of the  $\mathcal{S}_{20}$  start. Hatching and stippling in (c) depict regions where the average precipitation rate during the  $\mathcal{S}_{20}$  exceeds the 95<sup>th</sup> and 97.5<sup>th</sup> percentile, respectively, of all ERA-Interim wet days, defined as days with  $> 0.1$  mm precipitation. Hatching in (d) shows regions where at least 12 of the  $\mathcal{S}_{20}$  start in the same season. Crosses identify grid points for which the  $\mathcal{S}_{20}$  are further examined in Figs. 2–7.

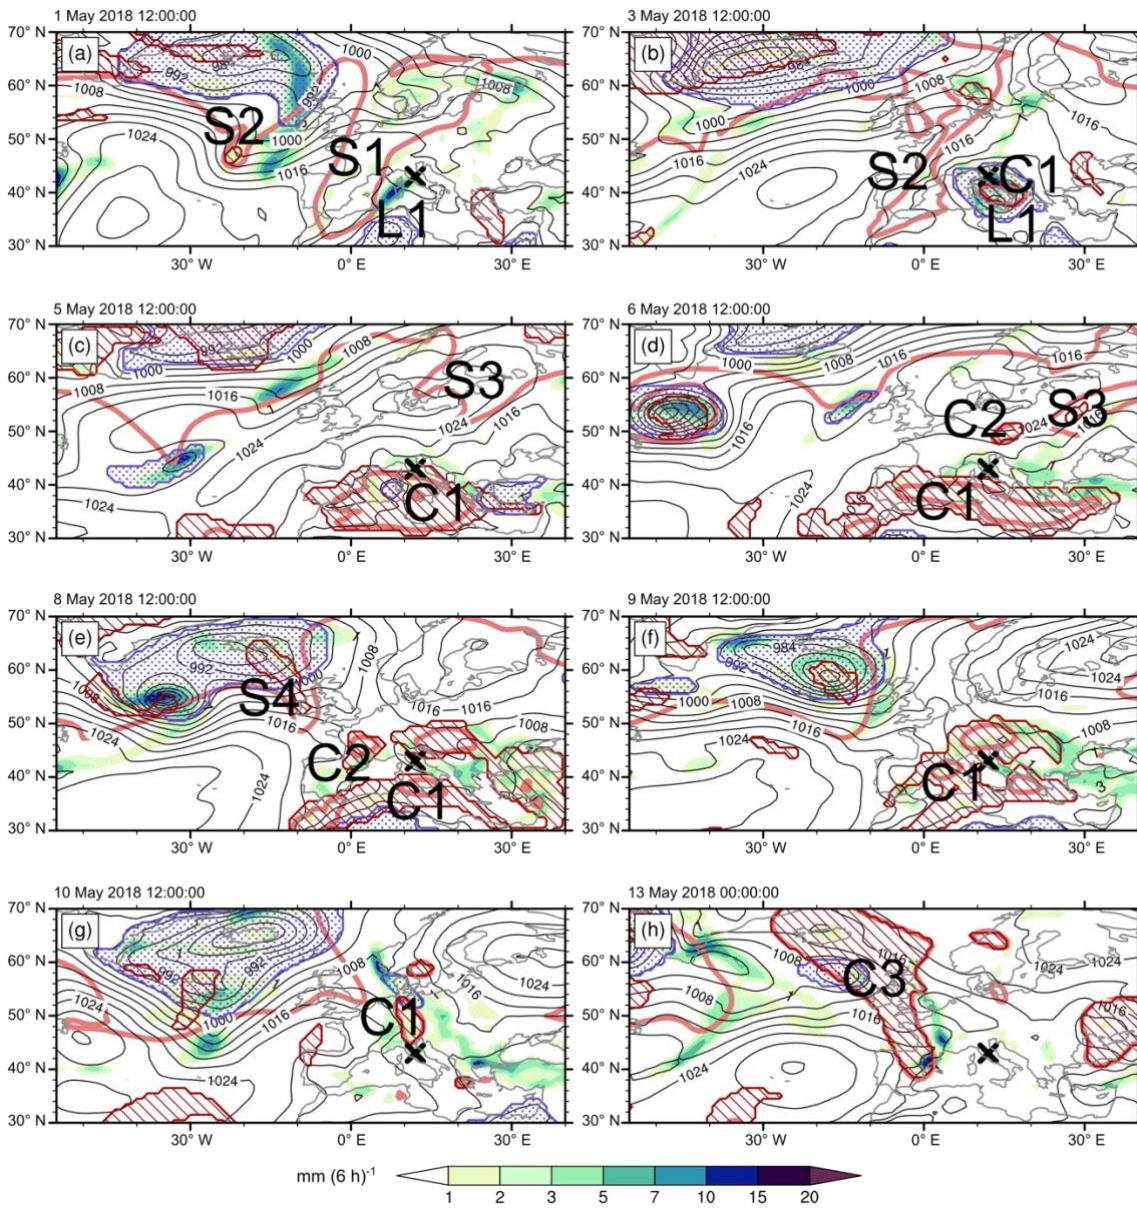

805 **Figure 2.** Time evolution of the wet spells illustrated in Figs. 3–6. The panels show the precipitation evolution during the longest wet spell  
 at (a)  $37^\circ$  E/ $57^\circ$  N, near Moscow, Russia in 2013, (b) at  $14^\circ$  E/ $66^\circ$  N, in Norway in 1989, (c) at  $12^\circ$  E/ $43^\circ$  N in Tuscany, Italy in 2018 and  
 810 at  $25^\circ$  E/ $48^\circ$  N, in Romania in 1988. Bars depict 6-hourly precipitation (multiplied by four) while the bold blue line depicts daily  
 precipitation accumulations. Daily precipitation is depicted for each day at 00:00 UTC and refers to the precipitation accumulation over  
 the preceding 24 hours. Red bars mark the onset and termination of each spell, while purple lines indicate the times for which fields are  
 shown in Figs. 3–6. Light vertical lines locate 00:00 UTC of each day.

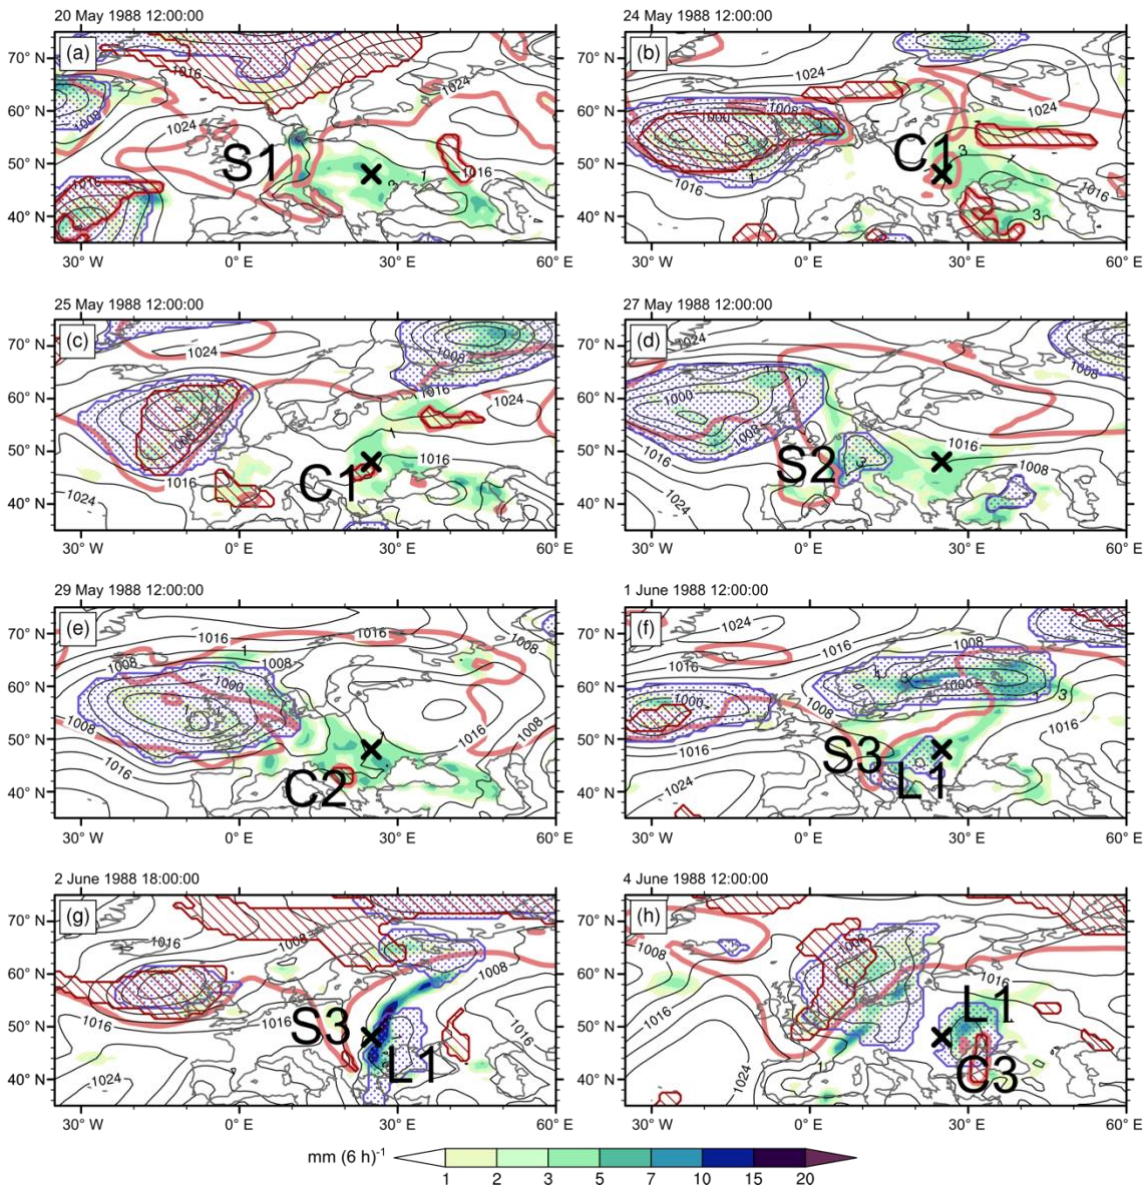

815 **Figure 3.** Synoptic evolution of the longest wet spell near Moscow, Russia [ $S_1$  ( $37^\circ$  E,  $55^\circ$  N)]. Shading depicts total precipitation accumulated over the preceding 6 hours. Light red contours show the 2 PVU dynamical tropopause on 320 K, while black contours show SLP (contour interval of 4 hPa). Cyclones are depicted by blue stippling and the red hatching depicts the projection of cutoff objects (see methods for details), whose outline therefore does not need to be co-located with the 2 PVU contour on 320 K. The black cross in all panels marks the grid point at  $37^\circ$  E/ $55^\circ$  N. Labels help to identify the features discussed in the main text. Panels are shown daily at 12:00 UTC from 20 to 27 July 2013.

820 **Figure 4.** As Fig. 3 but for the longest wet spell at 14°E/66°N in Norway [ $S_1$ (14° E, 66° N)]. The light red lines depict 2 PVU on 310 K. The valid time of each panel is shown in the top left.

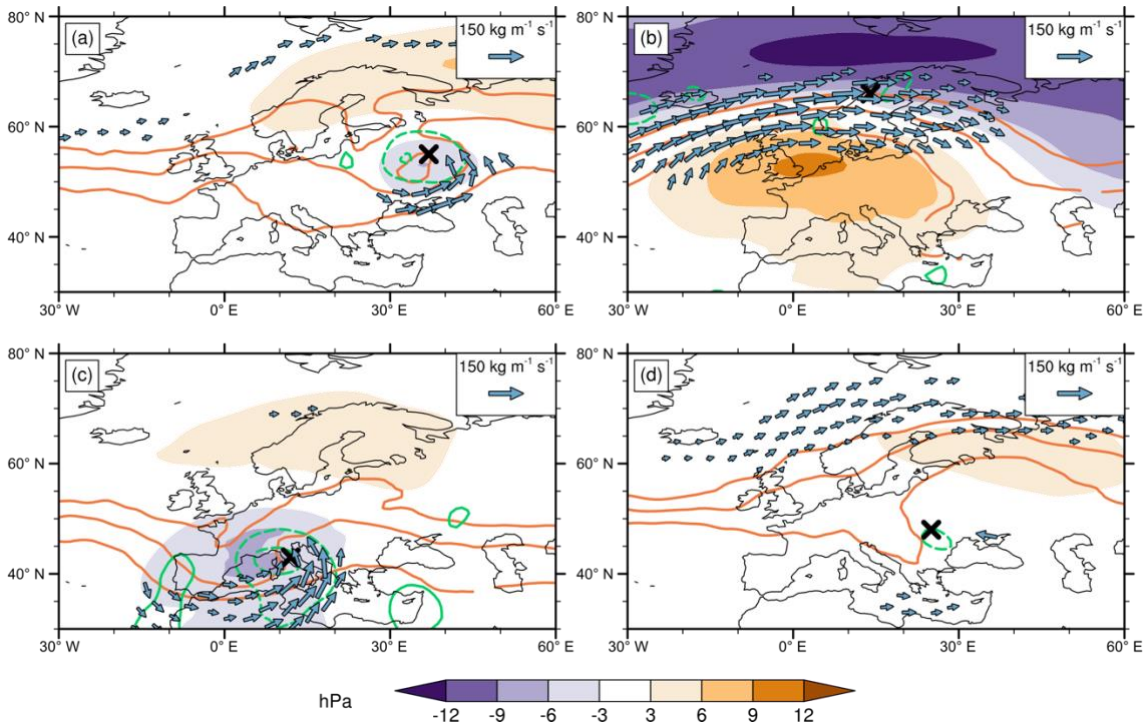

**Figure 5.** As Fig. 3 but for the longest wet spell at 12° E/43° N in Tuscany, Italy [ $S_1$ (12° E, 43° N)]. The light red lines depict 2 PVU on 320 K. The valid time of each panel is shown in the top left.

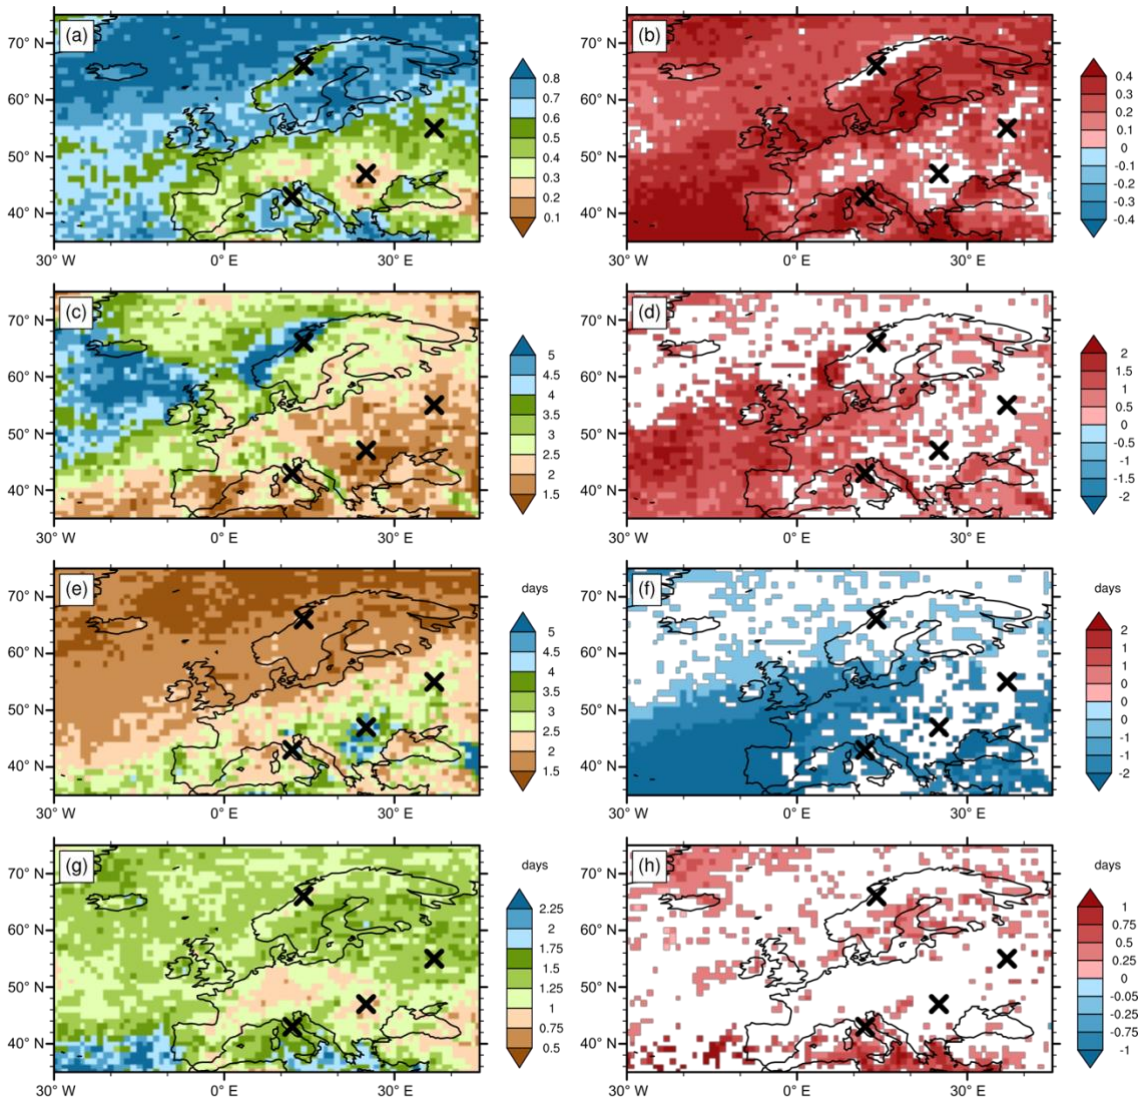

825 **Figure 6.** As Fig. 3 but for the longest wet spell at 25° E/48° N in Romania [ $S_1$  (25° E, 48° N)]. The light red lines depict 2 PVU on 320 K. The valid time of each panel is shown in the top left.

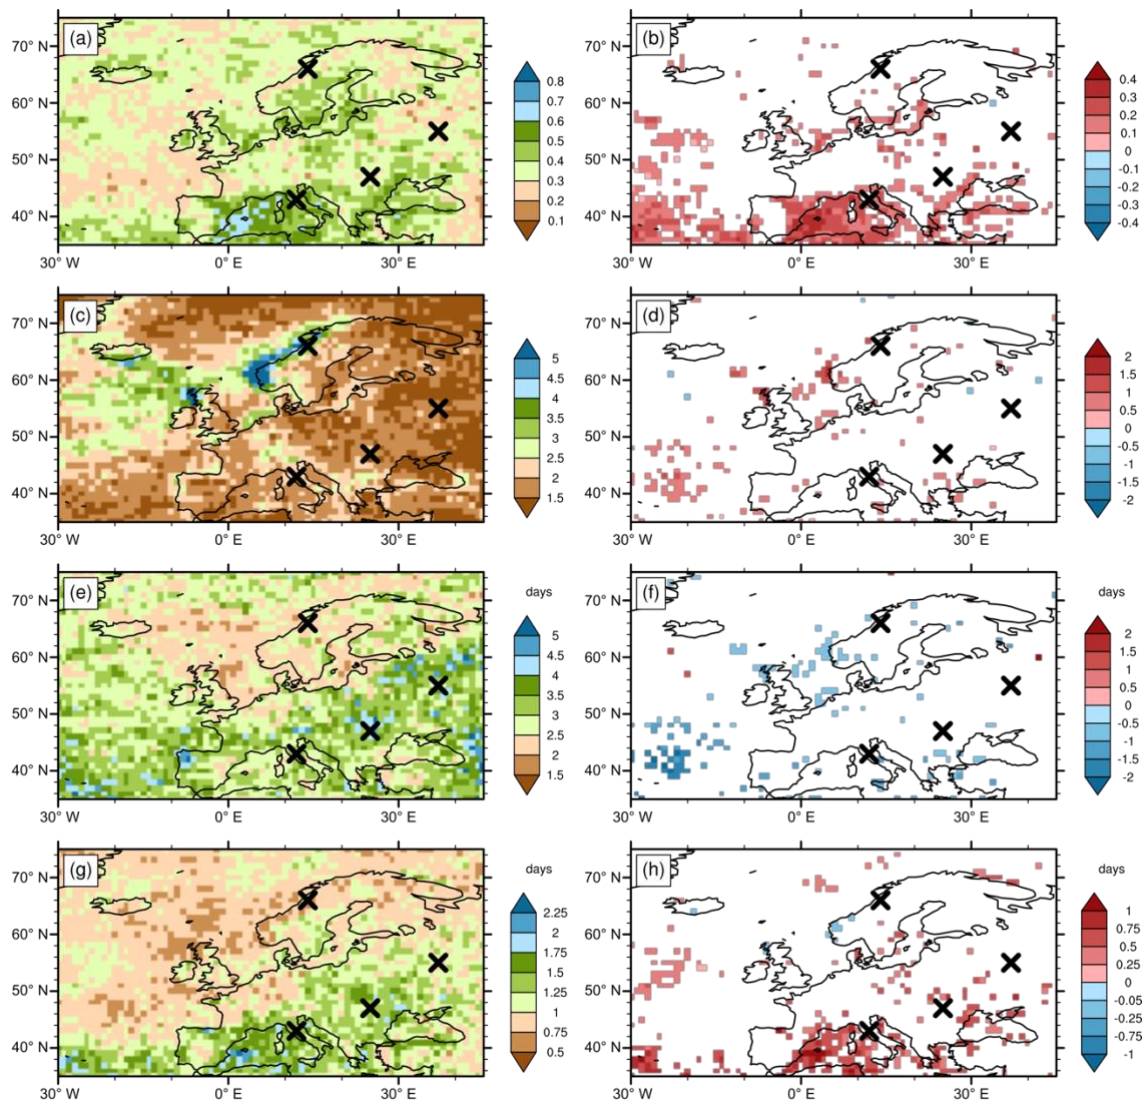

830 **Figure 7.** Composites of various fields for the (a)  $\mathcal{S}_{20}(37^\circ \text{ E}, 55^\circ \text{ N})$  (Moscow), (b)  $\mathcal{S}_{20}(14^\circ \text{ E}, 66^\circ \text{ N})$  (Norway), (c)  $\mathcal{S}_{20}(12^\circ \text{ E}, 43^\circ \text{ N})$  (Tuscany) and (d)  $\mathcal{S}_{20}(25^\circ \text{ E}, 48^\circ \text{ N})$  (Balkans). Shown are isentropic PV contours of 1, 1.5 and 2 PVU (orange, contours are masked where the respective isentrope intersects the orography on at least one time step of the respective  $\mathcal{S}_{20}$ ) on (a,c,d) 320 K and (b) 310 K, SLP anomalies (shading) and QG $\omega$  anomalies of -1.5, -1, -0.5 hPa hour<sup>-1</sup> (green dashed contours) and of +0.5, +1 and +1.5 hPa hour<sup>-1</sup> (green solid contours). Furthermore, vectors depict *IVT* anomalies whose magnitude exceed 30 kg m<sup>-1</sup> s<sup>-1</sup>. All anomalies are computed relative to a climatology containing data from all calendar days on which at least one of the  $\mathcal{S}_{20}$  at the respective grid point occurred for the 1979–2018 period, i.e., the climatologies vary between the four panels, depending on the seasonality and duration of the respective  $\mathcal{S}_{20}$ .

835

**Figure 8.** Cyclone characteristics during the  $\mathcal{S}_{20}$  (left column), and their respective anomalies (right column, see Section 2.5 for the technical definition of the four quantities and their climatological values). (a,b) the cyclone fraction,  $F_{cyclone}$ , i.e., fraction of total  $\mathcal{S}_{20}$  time steps with a cyclone, (c,d) number of distinct cyclones per  $\mathcal{S}_{20}$  spell,  $N_{cyclone}$ , (e,f) the cyclone period,  $P_{cyclone}$ , i.e., summed  $\mathcal{S}_{20}$  duration divided by number of distinct cyclones, and (g,h) the residence time,  $R_{cyclone}$ , i.e., the average time each distinct cyclone affects one of the  $\mathcal{S}_{20}$  spells. Statistically not significant values in panels (b,d,f,h) are masked out in white (see Section 2.5 for details).

840

**Figure 9.** As Fig. 8 but for cutoffs.
