**Correspondence:** Lina Boljka (lina.boljka@uib.no)

**Abstract.** Tropical Pacific is home to climate variability on different timescales, including El Niño Southern Oscillation (ENSO) – one of the most prominent quasi-periodic modes of variability in the Earth’s climate system. It is a coupled atmosphere-ocean mode of variability with a 2-8-year-timescale and oscillates between a warm (El Niño) and a cold (La Niña) phase. However, the dynamics of ENSO is complex, involving a variety of spatial and temporal scales as well as their interactions, which are not necessarily well understood. We use a recently developed nonlinear and nonstationary multivariate timeseries analysis tool – multivariate empirical mode decomposition (MEMD) – to revisit quasi-periodic variability within ENSO. MEMD is a powerful tool for objectively identifying (intrinsic) timescales of variability within a given system. We apply it to reanalysis and observational data as well as to climate model output (NorCPM1). Observational/reanalysis data reveal a quasi-periodic variability in the tropical Pacific on timescales  $\sim 2-4.5$  years. We then test different conceptual oscillator models from literature and find that  $\sim 2-4.5$ -year variability can be related to ENSO’s recharge-discharge and simplified West-Pacific conceptual oscillator models. The latter has not been considered before and it occurs only on this timescale, however it is not necessarily well represented in NorCPM1. Additionally, the  $\sim 2-4.5$ -year variability in ENSO can be ‘predicted’ up to  $\sim 18$  months ahead, while predicting the full ENSO amplitude remains challenging.

## 1 Introduction

The dynamics of the tropical Pacific is typically characterised by ocean-atmosphere interaction, whereby atmospheric changes in winds can lead to changes in the distribution of warm and cold waters in the ocean that in turn impact the atmosphere. The variability in the tropical Pacific occurs on various timescales – from subseasonal to multidecadal (e.g., Maloney et al., 2008; Enfield and Mestas-Nuñez, 1999; Mestas-Nuñez and Enfield, 2001). One of the most prominent features in the tropical Pacific is the El Niño Southern Oscillation (ENSO), which is a quasi-periodic phenomenon occurring on (inter-annual) timescales of 2-8 years (e.g., Philander, 1990; Wang and Fiedler, 2006; Timmermann et al., 2018). ENSO events are characterized by warming sea surface temperatures (SSTs) during the development of El Niño (warm phase) and cooling of SSTs afterwards leading into La Niña (cold phase).

ENSO is associated with major changes in the precipitation distribution in the region (increased precipitation typically follows warmer SSTs; e.g., Wang and Fiedler 2006; Dai and Wigley 2000) as well as in the distribution of warm and cold waters in the upper ocean (warmer SSTs are associated with a deeper thermocline in the ocean). This has strong relevance for

the society (e.g., Wang and Fiedler, 2006; Santos, 2006; Lam et al., 2019) through modulation of food production (fishery, agriculture), weather-related disasters, and economy (e.g., Cashin et al., 2017; Guimarães Nobre et al., 2019).

Because of its impacts, modelling and understanding of ENSO have been important topics for decades. The first models that captured crucial dynamics and were able to skilfully predict ENSO were developed in the 1980's (Quinn, 1974a, b; Cane et al., 1986; Zebiak and Cane, 1987; Suarez and Schopf, 1988), and ENSO predictions have been continuously improving since (L'Heureux et al., 2020). To improve (long-term) predictions of ENSO and its impacts, it is important to study ENSO variability and associated physics. Indeed, ENSO can be described by several different processes and conceptual models that can yield/explain prediction skill on longer timescales.

First, one can use conceptual models based on red noise arguments, where relatively slow ocean variability is an 'integral' response to stochastic higher-frequency atmospheric (e.g., "weather") variability (following, e.g., Hasselmann, 1976; Frankignoul and Hasselmann, 1977). While this is an integral part of the dynamical coupling between atmosphere and ocean, Clement et al. (2011) argued that the thermodynamic air-sea coupling (via thermally coupled Walker mode) also matters. Also, atmospheric 'wind-forcing' can help triggering ENSO events, however the timescale of this 'forcing' is still debated (e.g., Roulston and Neelin, 2000; Capotondi et al., 2018) and its efficiency in triggering ENSO may depend on the background state (e.g., Lopez et al., 2013; Lopez and Kirtman, 2014; Timmermann et al., 2018). Nonetheless, these processes give the system some persistence and thus can be related to prediction skill on longer timescales.

Second, as ENSO is a quasi-periodic event (e.g., Wang et al., 2017) a part of its prediction skill likely comes from its internal quasi-periodic variability (e.g., Ghil and Jiang, 1998). Thus, ENSO's quasi-oscillatory dynamics has been studied extensively in the past, and the theories typically consist of positive (e.g., Bjerknes) and negative feedbacks between the atmosphere and ocean. The Bjerknes feedback (Bjerknes, 1969) refers to any decrease (increase) of trade winds that leads to reduced (enhanced) ocean upwelling (downwelling) and thus warming (cooling) in the eastern tropical Pacific leading to reduced (enhanced) zonal SST- and pressure-gradients, which in turn reinforce the initial increase (decrease) of the trade winds. This feedback alone would result in continuous warming (cooling) in the eastern tropical Pacific, therefore negative feedbacks are necessary for quasi-oscillatory behaviour in the eastern tropical Pacific (e.g., Wang et al., 2017).

To describe the interplay between the (Bjerknes) positive and negative feedbacks, several conceptual oscillator models have been proposed (e.g., Wang, 2018, see also section 3.2): (i) the delayed oscillator (e.g., Suarez and Schopf, 1988; Battisti and Hirst, 1989) that included reflected Kelvin waves at the western ocean boundary as a negative feedback; (ii) the recharge-discharge oscillator (e.g., Jin, 1997a, b; Burgers et al., 2005) that included Sverdrup transport as a discharge/recharge processes (negative feedback); (iii) the advective-reflective oscillator (e.g., Picaut et al., 1997; Wang, 2001a) that included advection and reflection of Rossby waves at the eastern ocean boundary as a negative feedback; and (iv) the Western Pacific oscillator (e.g., Weisberg and Wang, 1997; Wang et al., 1999) that included interactions with the West-Pacific wind-forced Kelvin waves as a negative feedback. These oscillators can all be viewed as part of the unified oscillator (Wang, 2001a, 2018, see also section 3.2).

The above oscillators describe different processes that can lead to an ENSO event. These processes generally involve changes in the thermocline depth, surface wind stress, and SST anomalies. Note that seasonal cycle can strongly affect ENSO-related

oscillations, since positive feedbacks are generally stronger in boreal autumn and negative feedbacks are stronger in boreal spring, i.e., it helps phase-locking of ENSO (e.g., Stein et al., 2010; Wengel et al., 2018). However, ENSO also has many flavours and can, for example, occur in the Eastern or Central Pacific (EP and CP ENSO, respectively; e.g., Kao and Yu 2009; Singh and Delcroix 2013; Zhang et al. 2019), and can occur on different timescales as well, e.g.: (i) a quasi-biennial (QB) ENSO with a  $\sim 2$  year timescale and (ii) a low-frequency/quasi-quadrennial (LF/QQ) ENSO with a  $\sim 4$ -year timescale (e.g., Jiang et al., 1995; Allan, 2000; Kim et al., 2003; Keenlyside et al., 2007; Bejarano and Jin, 2008; Jajcay et al., 2018; Froyland et al., 2021).

Due to a multitude of factors impacting ENSO (described above), its predictability remains challenging (e.g., Fedorov et al., 2003; L'Heureux et al., 2020). This is due to unpredictable atmospheric (stochastic) forcing, different local and remote factors that impact it (e.g., inter-basin interactions), and different spatial and temporal scales involved. All these processes impact the initial conditions, which ultimately determine the ENSO onset/magnitude and thus its prediction. Presently, we are able to predict ENSO reasonably well 6 months ahead, and in some (rare) special cases even up to 2 years ahead (e.g., Chen et al., 2004; Park et al., 2018; L'Heureux et al., 2020). Some further improvements of ENSO predictability are also possible by utilising machine learning and neural network algorithms (e.g., Ham et al., 2019, 2021; Dijkstra et al., 2019). However, to improve and extend ENSO's (general) prediction range, further physical understanding of this phenomenon is needed, and with it also model improvements (e.g., McPhaden, 2015; L'Heureux et al., 2020).

The main aim of this study is to explore intrinsic quasi-periodic variability of the tropical Pacific (and thus ENSO) on different timescales and thereby revisit the conceptual oscillator models of ENSO. This is done first by objectively splitting the tropical Pacific variability (using reanalysis/observational products) into different timescales (identify intrinsic variability). This then allows identification of potential oscillations and their timescales, as well as the physical mechanisms that contribute to the tropical Pacific (and thus ENSO) variability on the quasi-periodic timescales (following, e.g., Jin 1997a; Wang 2001a). To achieve this, many different methods have been used in the past, e.g., multi-channel singular spectrum analysis (MSSA), principal oscillation patterns (POPs), linear inverse model (LIM) (Broomhead et al., 1987; Hasselmann, 1988; Penland and Sardeshmukh, 1995; Ghil et al., 2002). However, these methods can be linear, stationary or both (Huang et al. 1998; Ghil et al. 2002; see also section 2.2), which can be a constraint for studying inherently nonlinear and non-stationary systems, such as the climate system.

Therefore, in this study we employ a recently developed nonlinear and nonstationary method for multivariate-timeseries filtering/analysis, called Multivariate Empirical Mode Decomposition (MEMD; Rehman and Mandic 2010). This method is a multivariate extension of the Empirical Mode Decomposition (EMD; Huang et al. 1998) and can identify common timescales across different timeseries and multi-dimensional fields (for details see section 2.2 and Appendices A, B). This method objectively extracts intrinsic modes of variability in the tropical Pacific without a pre-selection of timescales, and can be used for identifying potential quasi-oscillatory behaviour, as well as the physics related to the tropical Pacific (and ENSO) variability on different timescales (more in section 3, and Appendix B2). This knowledge can then be used for constructing conceptual oscillator models, as well as for further understanding of model biases, ENSO prediction, ENSO teleconnections across scales, and other processes (see sections 4 and 5).

The manuscript is structured as follows. Section 2 provides data and methods used in this study (Appendices A and B provide further details on methodology); section 3 explores the physical mechanisms (and conceptual oscillator models) relevant on different timescales with a focus on the timescales that are quasi-oscillatory; section 4 compares climate model data with reanalyses/observations and tests predictability of the quasi-oscillatory mode (see also Appendix C). Conclusions are given in section 5.

## 2 Data and Methods

### 2.1 Data

In this study we focus on the variability of ENSO using MEMD algorithm (described below). For this, we analyse monthly mean data of four different variables: sea surface temperature (SST) from HadISST observational dataset (Rayner et al., 2003), surface zonal wind stress ( $\tau_x$ ) and thermocline depth (i.e., the depth of the 20°C isotherm) both from SODA2 ocean-reanalysis dataset (Carton and Giese, 2008). These three variables are used to assess the ENSO dynamics as these quantities typically play a leading role in the onset and decay of ENSO events, and are typically used in the oscillator models that explain ENSO dynamics (see section 3.2 and, e.g., Wang, 2018). The data are analysed in the tropical Pacific (110°E - 65°W, 25°S - 25°N) over the period 1871-2010 for which all datasets are available. Note that surface wind stress and the ocean subsurface data reconstructions in the 19<sup>th</sup> and early 20<sup>th</sup> century are less reliable than in the late 20<sup>th</sup> century due to sparser data coverage, thus the results presented here are only as accurate as these reconstructions can be (Wittenberg, 2004; Crespo et al., 2022). We use the early record data here as the (simple) prediction model used in section 4.2 requires as much data as possible, and the early record does not affect the overall results of this study. In fact, results of the recent decades are consistent with previous studies (see below).

The MEMD analysis (described below) is performed on all fields simultaneously with SST at the highest resolution (1° in latitude and longitude), whereas thermocline depth and  $\tau_x$  (both 9° resolution in longitude, 5° resolution in latitude) have much lower resolution. This gives greater weight to SST data in the analysis, and less towards the other variables, such that the mode does not change significantly by adding other variables in the analysis (i.e., results below for the SSTs are similar whether we use SSTs alone or together with other fields). This is because here we are primarily interested in the quasi-periodic behaviour in SSTs, since SSTs are used for defining ENSO (e.g., in Niño3 region). SSTs are also typically smoother than other fields – this is especially true for wind stress, which is strongly affected by the “noisy” atmospheric variability. This ensures that modes that emerge from MEMD analysis are representative of quasi-periodic variability in SSTs (and thus ENSO), while the rest of the variables are “enslaved” to SST variability. Thus, the other variables can help explaining the dynamics of ENSO (SST variability) on a specific timescale. Note that MEMD can be sensitive to input data, thus we must carefully consider the input data structure (relevant to a specific study).

In section 4 below we also analyse model data, namely the first ensemble member (i.e., r1i1p1f1; other ensemble members were qualitatively similar) of the NorCPM1 historical simulation (Bethke et al., 2019, 2021). As in observational data, we use

**Table 1.** Tropical Pacific regions used for computing timeseries (see text for details).

Region	Latitude Range	Longitude Range
Niño3	5°S - 5°N	150°W - 90°W
Niño4	5°S - 5°N	160°E - 150°W
Niño5	5°S - 5°N	120°E - 140°E
Niño6	8°N - 16°N	140°E - 160°E
Pacific mean	5°S - 5°N	120°E - 90°W

model's  $\tau_x$ , thermocline depth, and SSTs in the MEMD analysis. For consistency, we use the time period 1871-2010 in the model as well.

130 While the SSTs, thermocline depth, and  $\tau_x$  play an important role in the ENSO dynamics, it is specific regions (see Table 1) that are more relevant for the oscillator models (e.g., Wang, 2001a, 2018; Burgers et al., 2005). Namely, we average  $\tau_x$  over Niño4 and Niño5 regions separately, thermocline depth over Niño6 region (off-equatorial thermocline depth) and over the tropical Pacific (Pacific mean), and SSTs over Niño3 region (again, see Table 1; see also Fig. 3 in Wang et al. 1999).

Before performing the analysis, we detrend the data and remove its seasonal cycle, which is done the following way (cf.,  
135 de la Cámara et al., 2019). First, we calculate 30-year means centered on every  $10^{th}$  year for each individual month. This yields one value for each individual month every 10 years. Then, we interpolate between these values (of every  $10^{th}$  year) to obtain yearly time series, again for each individual month. This yields a smooth seasonal cycle that includes a trend and seasonal cycle for every month in the record. Detrended and deseasonalized data are then computed as the difference between the original monthly timeseries and the smooth trend/seasonal cycle. We do this at every grid point and for every variable separately.

140 This is done to avoid domination of the seasonal cycle or trend in the statistical analysis below, even though the method presented below can generally extract nonlinear trends by itself. Note that this means that we cannot assess the impact of long-term variability or seasonal cycle on ENSO variability in this study, but the latter may still be present indirectly as it helps phase-locking of ENSO (e.g., Stein et al., 2010; Wengel et al., 2018).

## 2.2 (Multivariate) Empirical Mode Decomposition

145 To analyse the ENSO dynamics and relevant data, we use Multivariate Empirical Mode Decomposition (MEMD). This method was first introduced by Rehman and Mandic (2010) as a multivariate extension of the Empirical Mode Decomposition (EMD; also called Hilbert-Huang transform). The EMD was introduced by Huang et al. (1998) as an alternative method for time-filtering of the one-dimensional (1-D) timeseries that is entirely data adaptive, nonlinear, and nonstationary, and thus more appropriate for analysing nonlinear and/or nonstationary data – the main advantage of this method. This is in contrast to some  
150 other methods (e.g., singular spectrum analysis, wavelet analysis, Fourier transform, principal component analysis, nonlinear Laplacian spectral analysis, POPs, LIM), which do not necessarily have a multivariate extension, and/or are either linear,

stationary, or both. The EMD is based on Hilbert transform and takes advantage of the instantaneous frequency, allowing a ‘local’ extraction of modes of variability. Each mode that the EMD extracts consists of two elements: (1) typical timescale of the mode, i.e., average instantaneous frequency of the mode (see below); and (2) the timeseries of the mode. The modes are ordered from the highest (shortest) to the lowest (longest) frequency (period/timescale). Since these modes and their timescales are identified objectively without any ‘first guess’, another main advantage of this method (and its multivariate extension) is objective identification of intrinsic timescales and their timeseries within the given data. Note that modes that emerge are largely independent with only small correlations between them.

For simplicity, consider first the EMD method (i.e., 1-D version) as it has a relatively simple implementation (for details see Huang et al., 1998): (i) first, we identify local minima and maxima of the input (1-D) timeseries and create an envelope by interpolating between the subsequent maxima (upper envelope) and between subsequent minima (lower envelope); (ii) then we obtain an average envelope from the upper and lower envelope and subtract it from the timeseries data; (iii) the subtracted data (i.e., original data minus the average envelope) become the first mode of variability with the signal of the highest frequency in the dataset, whereas the average envelope can be analysed further; (iv) repeat steps (i)-(iii) for the average envelope until only a trend (residual) remains, i.e., until a condition of at least 2 extrema in the dataset can no longer be satisfied. The modes of variability (i.e., timeseries) obtained through this process are called intrinsic mode functions (IMFs), and their instantaneous timescale is characterised by the time-lapse between two subsequent extrema (and IMF’s mean timescale is an average over the instantaneous values). Each IMF also has to satisfy two criteria: (a) the number of extrema and the number of zero-crossings differs at most by one; and (b) the mean value of the envelope of the IMF is zero. Note that the procedure from (i) to (iv) does not necessarily satisfy (a)-(b) immediately, thus additional sifting process is used that requires a stopping criteria to ensure physical meaning of the IMFs. The stopping criteria can be based on the standard deviation of each IMF, on the maximum number of iterations, etc., which set tolerance and confidence limits for the IMF (for details see Huang et al., 1998; Rilling et al., 2003; Huang et al., 2003).

The MEMD method (Rehman and Mandic, 2010) is a generalisation of the EMD to multivariate datasets of more than two timeseries (for bivariate and trivariate data separate methods exist; Rilling et al. 2007; Rehman and Mandic 2010). The method solves a similar problem as in (i)-(iv) but on an N-Sphere, which is much more complex, and the method retains similar stopping criteria for the sifting process. For further details on and visualisations of the method the reader is referred to Rehman and Mandic (2010). The code for the method is freely available on Github (<https://github.com/mariogrune/MEMD-Python->; similarly for the EMD discussed above: <https://github.com/laszukdawid/PyEMD>), and the user ultimately only decides about the stopping criteria, which are here set to their “fix\_h” parameter, following Huang et al. (2003) who suggest that limiting iterations yields better-behaved IMFs than other stopping criteria. Here, we limit the number of iterations to 15 (parameter “n\_iter” is 15), though other values were tested and a range for “n\_iter” around 10-30 yielded similar results, suggesting some convergence for the *significant* modes of variability. Note that at higher frequencies we find mode-mixing in our MEMD analysis where timescales are not clear (here, this occurs on timescales shorter than about 8 months), especially with larger number of iterations. However, the significant modes of variability on interannual timescales that are of interest here are largely unaffected by this.

The MEMD ultimately extracts timescales *common to all* input timeseries (i.e., synchronises signals) and provides IMFs according to these timescales, which are consistent across the input timeseries (to visualise this, see below and supplementary Figs. S7-S11, Tables S1-S2, and section S.3 for an idealised example). This is an additional property of MEMD relative to its 1-D version (EMD). Note that the use of IMFs obtained via MEMD analysis will depend on application—here, we analyse principal components of a 3-D field to extract quasi-oscillatory modes of variability (the whole procedure is described below and in Appendices A, B). In this study, we use the MEMD method because of its nonlinear and nonstationary properties, and its property to detect quasi-periodic signals without pre-selecting (filtering for) a frequency band (a constraint with, e.g., singular-spectrum analysis), and without any periodic signal or basis of functions specifications (a problem with, e.g., Fourier transform and wavelet analysis).

Even though EMD and its 1-D extension Ensemble EMD (EEMD; Wu and Huang 2009) have been applied in climate science in various applications, e.g., for smoothing, filtering, extracting trends, variability, and testing for red noise distribution of climate data (e.g., Duffy, 2004; Wu et al., 2007; Franzke, 2009; Lee and Ouarda, 2011; Qian et al., 2011; Franzke and Woollings, 2011; Franzke, 2012; Ezer and Corlett, 2012; Ezer et al., 2013; Wang and Ren, 2020), it has not been explicitly used for extracting quasi-periodic signals. Moreover, the MEMD has only been applied to an analysis of the atmosphere-ocean coupling strength (Alberti et al., 2021) in climate science, which was done in a more idealised setting from the present study – used to analyse ENSO dynamics. Therefore, (in addition to analysis of ENSO dynamics) we also perform extensive analysis of the method itself and compare it to the basic band-pass filtering (5<sup>th</sup> order Butterworth filter) and to Fourier transform analysis. This shows that MEMD’s results are consistent with other methods, but can also extract modes of variability in a more objective way (see below and Appendices A, B).

As with all statistical methods, also (M)EMD has drawbacks that we must be aware of (e.g., Stallone et al., 2020). Because it is a statistical method we must always test if the modes we find using (M)EMD are physical, and also check for convergence (stability) of the modes using different parameter sweeps (as mentioned above). Much like other timeseries-filtering methods, also (M)EMD has issues at the edges of the timeseries, which can lead to “travelling waves” and thus unrealistic peaks in the timeseries (e.g., Stallone et al., 2020). There is also a common issue of mixing modes (as mentioned above) where one (real) mode is split into two or more modes if we choose “wrong” parameters (e.g., Huang et al., 1999, 2003; Stallone et al., 2020), but this is also an issue when there is no clear timescale-separation. We have tested different sweeps of parameters and have ultimately decided on the ones specified above, as they suggested some stability and the results were realistic and comparable to other methods (note that for other applications different parameter sweeps may yield better results). Therefore, we continue from hereon with the description of implementation of the MEMD method and later we use it to understand the ENSO dynamics on different timescales.

### **Obtaining modes of variability via MEMD**

As mentioned in Sect. 2.1, we use 3-D data relevant for ENSO dynamics, i.e.,  $\mathbf{A}(t, y, x)$  (with  $t$  as time,  $y$  as latitude,  $x$  as longitude,  $\mathbf{A}$  as the selected variable(s)/field(s); bold letters represent matrices), as basis for the MEMD analysis. We first remove the smooth trend/seasonal cycle (described above; see also de la Cámara et al., 2019) from  $\mathbf{A}$  to get a temporal anomaly,

$\mathbf{A}'$ . Since here we use more than one variable (i.e., SSTs, surface wind stress, thermocline depth) in the analysis, we concatenate the different variables in their spatial dimensions, i.e., we get  $\mathbf{A}'(t, y = y_1 + y_2 + \dots, x = x_1 + x_2 + \dots)$  (with subscripts 1,2,... representing spatial dimensions of the different variables). Note that we also divide data by their standard deviations ( $\sigma$ ; done separately for each variable and at each grid point) before concatenating them. Then we reduce the dimensionality  
225 by computing spatial patterns (empirical orthogonal functions, EOFs) and their timeseries (principal components, PCs) via singular value decomposition (SVD). We only retain the first 20 PCs that explain the majority of the variance in the field  $\mathbf{A}'$ . The PCs are then ultimately used as input data for the MEMD algorithm as described in Appendix A in detail. The modes that emerge from the MEMD analysis can become spatio-temporal modes of variability (IMFs) by reconstructing the fields from PCs and EOFs (Appendix A) for each IMF. Here, we identify 22 IMFs that are ordered by frequency from highest (IMF1) to  
230 lowest (IMF22) with the last 22<sup>nd</sup> mode typically representing a trend.

To compute an index, such as Niño3, we can average over a x-y region (Table 1) from spatio-temporal IMFs to obtain timeseries of, e.g., SST (Niño3) for each IMF separately (see supplementary Figs. S7-S11 for timeseries and Table S1 for their timescales). This yields the IMFs of an index (e.g., Niño3) corresponding to an equivalent index computed from input data ( $\mathbf{A}'$ ).

235 Once we have computed the IMFs from the input data, we need to test if they are significant. The importance of each IMF can be assessed by computing variance explained of each IMF relative to the input field (e.g., retaining those IMFs that explain more than 0.1% variance) or through other significance tests (e.g., white noise test; Appendix B1; Wu and Huang, 2004). As the interest in this study is in potential oscillatory behaviour in the ENSO region, we seek IMFs that pass a red noise threshold, since the monthly sea surface temperature data typically follow a red noise distribution. The red noise test is described in  
240 Appendix B2, and the results are shown in Fig. B1 (incl. a white noise test for comparison). The timescales of significant modes, identified via Fig. B1, fall well within the significant timescales identified via a typical power spectrum (via Fourier transform) analysis in Fig. B3 (for more see Appendix B2).

The results from Appendix B2 suggest that there are one to two significant modes of variability in the ENSO region, namely the 12<sup>th</sup> and 13<sup>th</sup> mode (IMF12, IMF13). Recall that any potential oscillatory timescales longer than 30-years were removed  
245 via detrending mentioned above, and are thus not considered here. The two significant modes of variability (i.e., IMF12 and IMF13) in the ENSO region have average timescales of about 22 and 34 months (i.e., 2-3 years), respectively, and are therefore well within the typical ENSO timescale range (2-8 years). Such timescales (with their uncertainty ranges; see below) are consistent with both QB and LF/QQ ENSO (e.g., Jiang et al., 1995; Jajcay et al., 2018). We find that the quasi-periodic mode of variability with 34 months average period (IMF13) is much clearer (than IMF12), which is consistent with 'more periodic'  
250 LF/QQ ENSO (Jiang et al., 1995). Spatial pattern of the significant mode with 34 months timescale (IMF13) is provided in Fig. 2, which shows that it indeed resembles ENSO spatial pattern, and is further discussed in section 3. Note that the spatial pattern of the 22 months mode (IMF12; see Fig. S2 in supplement) looks qualitatively similar, but it is only weakly significant. On longer timescales, we do not find any behaviour that would be discernible from red noise, suggesting that the lower-frequency range of ENSO (timescales longer than  $\sim 4.5$  years) (Allan, 2000; Jajcay et al., 2018, e.g.) is better represented by red noise  
255 and likely less predictable than QB or (especially) LF/QQ ENSO.

Even though the results from Appendix B2 provide ‘significant’ IMFs, MEMD remains a statistical method and thus further analysis is required to identify whether its modes have any physical meaning. If IMFs are physical, any inferred information could be used for improving our climate models, long-term prediction, understanding the teleconnections, the underlying physics/variability of the field we are interested in (e.g., ENSO), etc. This is addressed in the following sections (3, 4) through  
260 the analysis of ENSO dynamics and its conceptual oscillator models in observations and a climate model.

### 3 Variability and dynamics of ENSO

In the previous section we have established that the Niño3 index in the tropical Pacific exhibits two quasi-periodic modes of variability with average periods  $\sim 2$ -3 years (via MEMD analysis; note that from hereon we only consider the results from the MEMD analysis). The timeseries of the two IMFs (IMF12 and IMF13) are shown in Fig. 1 (red dotted and dashed lines  
265 respectively), along with their sum (black dashed line) and a band pass (17-52.5 months) filtered Niño3 index (black solid line).

Fig. 1 shows that the period/frequency of the two modes is not constant (i.e., varies in time; see below), thus we also specify a range of periods/frequencies for the two modes. The mean periods of IMF12,13 with their ‘uncertainty’ ranges (in square brackets) are: 22 [17, 32] (IMF12), and 34 [25, 52.5] (IMF13) months. These ranges are defined based on the 6.7<sup>th</sup> and 93.3<sup>rd</sup> percentiles of IMF12, IMF13’s instantaneous period/frequency values, which roughly correspond to  $\pm 1.5\sigma$  (instantaneous periods).  
270 Fig. S1 (supplement) shows power spectra of IMF12 and IMF13, which visualise the range of periods the two modes have. Note that instantaneous period/frequency can be obtained via Hilbert transform (see Eq. (B4) in Appendix B1). This range was chosen as it yielded the best results, but other (reasonable) percentile ranges give qualitatively similar results. We then use these period/frequency ranges to perform a band pass filter (via 5<sup>th</sup> order Butterworth filter) consistent with the individual modes (e.g., 25-52.5 months band of IMF13 is used to construct band-pass filtered index composites in Fig. 3b; more below), as well  
275 as a band-pass filter consistent with the sum of the modes where the band-pass range encompasses periods of both significant modes, i.e., 17-52.5 months (e.g., used to construct black solid line in Fig. 1).

Timeseries of the sum of IMFs (black dashed line) and band passed index (black solid line) in Fig. 1 largely agree, i.e., their correlation is 0.96. However, also the individual modes show very good agreement with the band-passed index with correlations of 0.69 (IMF12) and 0.83 (IMF13), which can be increased further if we consider only the specific IMF’s timescale  
280 range (specified above) when band-passing the Niño3 index. This merely confirms that MEMD results are consistent with other filtering methods.

Additionally, timeseries of Niño3 index extracted from IMF12,13 (Fig. 1) are largely consistent with the modes identified in Jiang et al. (1995) (their Fig. 9a), who used MSSA analysis, and with Wang and Ren (2020) (their Fig. 3), who used EEMD on Niño3.4 index. IMF13 is also similar to Froyland et al. (2021) 4-year mode (their Fig. 10), who used operator-theoretic  
285 approach. Also, the average periods of the ‘significant’ modes of variability (IMF12,13) in this study are typically lower than in other studies, however please recall that we used much longer timeseries and that timeseries of IMFs are nonstationary. Thus, within the overlapping time periods (e.g., recent decades), the timescale (and corresponding timeseries) is generally consistent across different studies. These similarities provide further confidence in the results presented below. Note that these studies

have focused on different ENSO timescales and associated different spatial patterns during QB and LF/QQ ENSO events, but  
290 have not considered the conceptual oscillator models that we analyse below.

The period-ranges provided above (see also Fig. S1) suggest that there is some overlap between the period/frequency bands, which is a result of nonlinear and nonstationary evolution of the modes (period is not constant as seen in Fig. 1). Indeed, there is a low (yet statistically significant) correlation between the two modes ( $\sim 0.27$ ). Thus, in some time-windows the two IMFs can describe the variability of a similar timescale (e.g., similar time evolution in Fig. 1 around years 1902-3, 1923-7, 1983,  
295 1997), but in other time-windows they describe variability on different timescales. Despite changing periods, the two IMFs overall pass the red noise threshold and are therefore still considered significant and thus *quasi*-periodic (Appendix B2).

Fig. 1 also shows that in some decades the band-pass-filtered Niño3 index (black solid line) is more consistent with the lower frequency IMF13 (red dashed line; approx. 1870-1917, 1938-1950, 1968-2000) and in other periods with the higher frequency IMF12 (red dotted line; approx. 1917-1938, 1950-1968, 2000-2010). This is likely consistent with the interdecadal shifts in the  
300 frequency of ENSO (Hu et al., 2017, 2020) that have occurred around years 1970 (from higher frequency to lower frequency) and 2000 (from lower frequency to higher frequency), and can also be seen earlier in the record in Fig. 1. We can also see interdecadal changes in amplitude of ENSO modes, i.e., middle panel (periods 1920-1965) in Fig. 1 compared with top and bottom panels (periods 1870-1920, 1965-2010). This is somewhat consistent with Crespo et al. (2022), who found reduced amplitude of ENSO during 1901-1931 and 1935-1965 periods relative to post-1970 period.

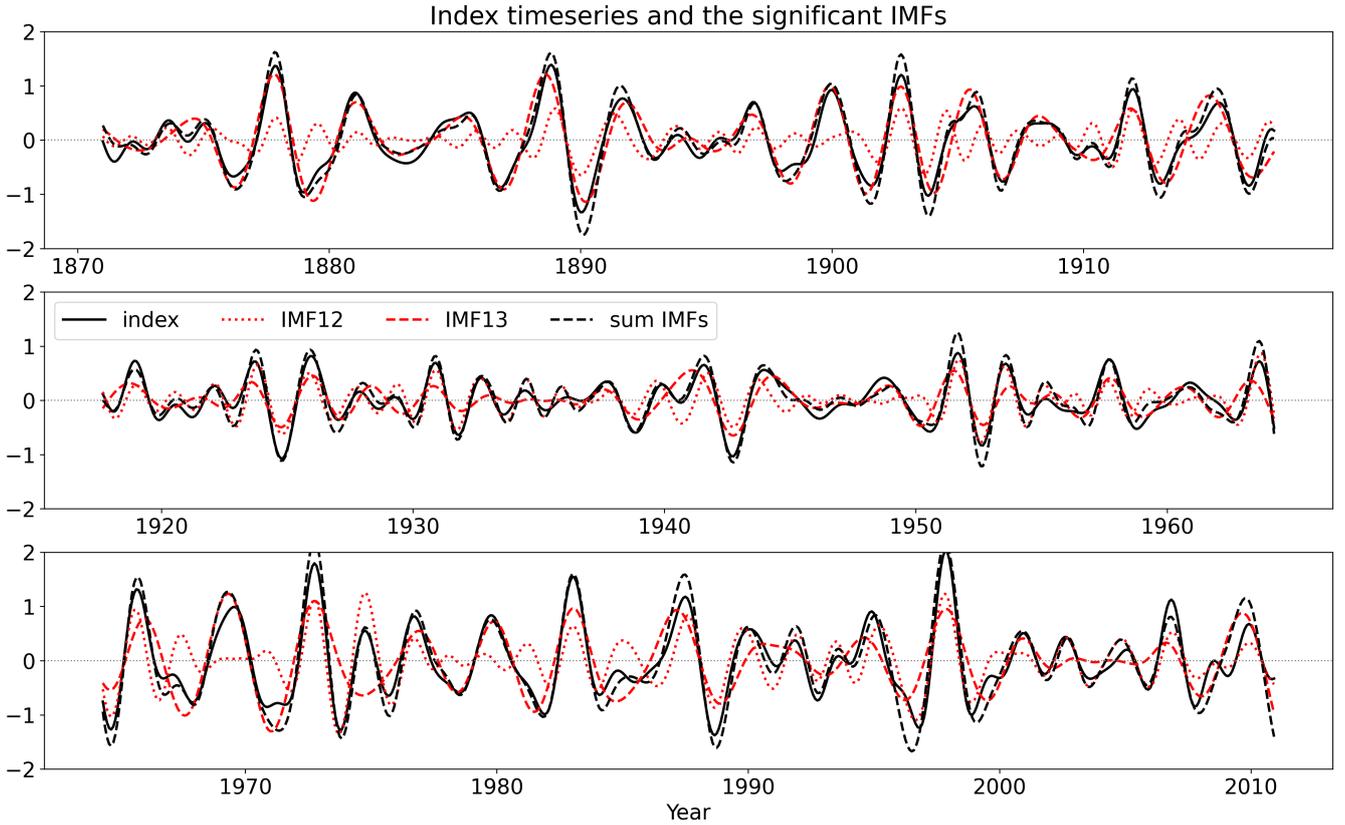

Note that the magnitude of ENSO ultimately depends on all underlying modes of variability in the tropical Pacific (not just  
305 on the IMFs discussed here). In fact, we find  $\sim 5$  modes (i.e., IMFs 11-15 here) with timescales ranging from  $\sim 1$  to  $\sim 12$  years (assessed via 6.7<sup>th</sup> and 93.3<sup>rd</sup> percentiles as above) that can reproduce the majority of ENSO variability (not shown), but the rest of these modes (i.e., IMF11,14,15 here) are consistent with red noise.

Fig. 1 also shows that weak Niño3 events have either small amplitudes (e.g., 1933-7) of both IMFs or opposite amplitudes  
310 (e.g., 1908-11), whereas strong Niño3 events generally show a constructive interference or mode-combination (e.g., 1997, a super-El Niño event), which is consistent with, e.g., Slawinska and Giannakis (2017); Jajcay et al. (2018); Wang and Ren (2020); Froyland et al. (2021).

Note that the band-pass range here was chosen using an ‘objective’ data-driven approach, which shows that MEMD can be used as an effective band-pass filter method. This is supported by a good agreement between the band-passed data and the  
315 IMFs (similarly, with spectral analysis; Appendix B2.2; Fig. B3), which suggests consistency between modes obtained via MEMD and other statistical methods. This provides grounds for using MEMD for further analysis of ENSO dynamics or, more specifically, for revisiting ENSO conceptual oscillator models, which we turn to next.

### 3.1 Observational evidence

ENSO evolution is primarily related to the evolution of the ocean surface wind stress ( $\tau_x$ ), thermocline depth and the SSTs  
320 in the tropical Pacific (e.g., Wang, 2018). Their relationship is demonstrated with map phase composites of IMF13 in Fig. 2, where shading represents SST anomalies, contours represent the thermocline depth anomalies (solid contours represent positive

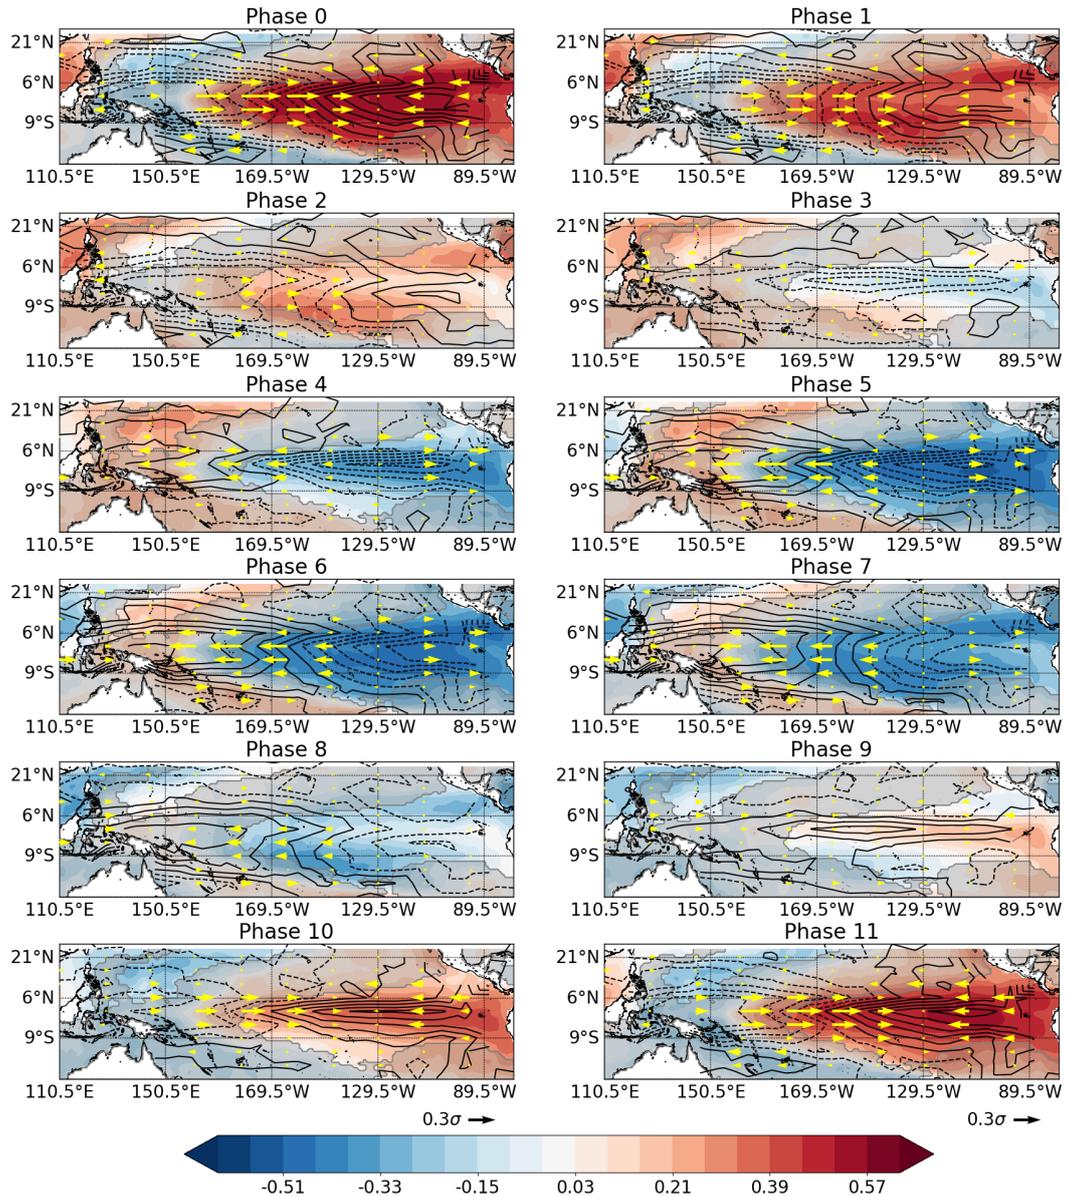

**Figure 1.** Timeseries (1871-2010) of band-pass filtered (17-52.5 months) Niño3 index (black solid line), IMF12 obtained via MEMD (red dotted line), IMF13 obtained via MEMD (red dashed line), and the sum of the two IMFs (black dashed line).

values and deeper thermocline), yellow arrows represent  $\tau_x$  anomalies, and grey shading represents grid points of the SSTs that do not pass the red noise threshold. All values are standardised (i.e., divided by standard deviation).

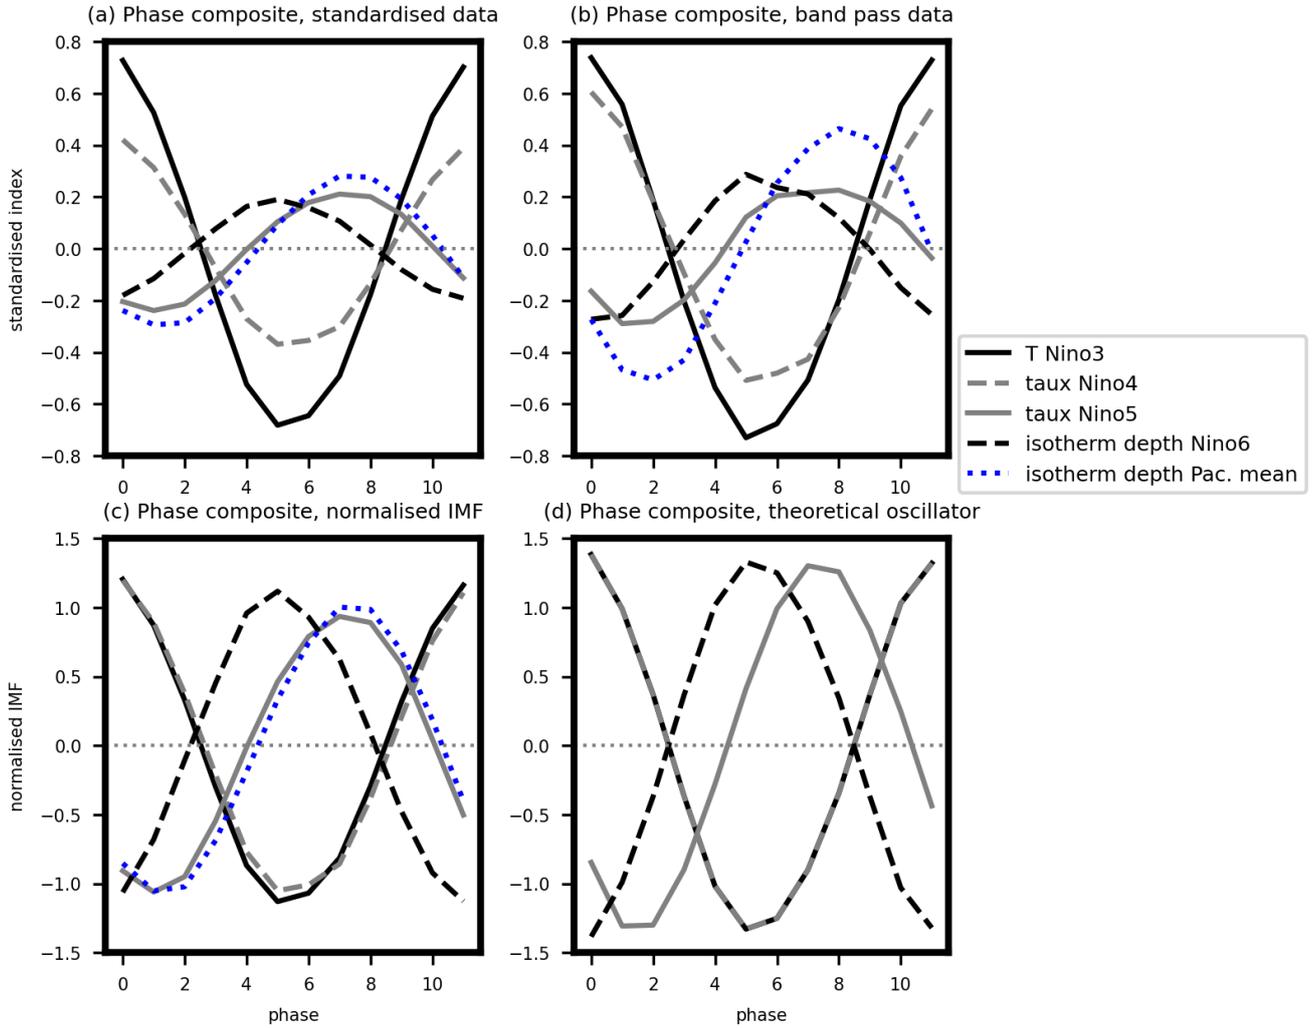

The phase composites are computed using instantaneous phase of the SST (Niño3) timeseries (from IMF13) that we can obtain via Hilbert Transform (Appendix B1, Eq. (B4)). This ‘assigns’ every point in the SST (Niño3) timeseries a phase between 0 and 360 degrees, which can then be split into 12 phases (marked phase 0 through 11; e.g., phase 0 is 0-30°, ..., phase 11 is 330-360°) and all points in timeseries (of 1-D or 3-D fields) belonging to a specific phase are then averaged to form phase composites shown in Fig. 2 (see also Fig. S2 for IMF12). Line phase composites shown below are constructed similarly. SST (Niño3) is chosen as index here as conceptual models discussed below (section 3.2) involve SST (Niño3).

Fig. 2 shows a typical cycle of ENSO in the tropical Pacific (on a  $\sim 3$ -year timescale), which can be summarised also with line phase composites (Fig. 3a,c) of timeseries averaged over specific regions (as labeled; see also Table 1) of the tropical Pacific (e.g., Wang, 2018). Here, we analyse SSTs (Niño3),  $\tau_x$  (Niño4),  $\tau_x$  (Niño5), thermocline depth (Niño6), and thermocline depth (Pacific mean).

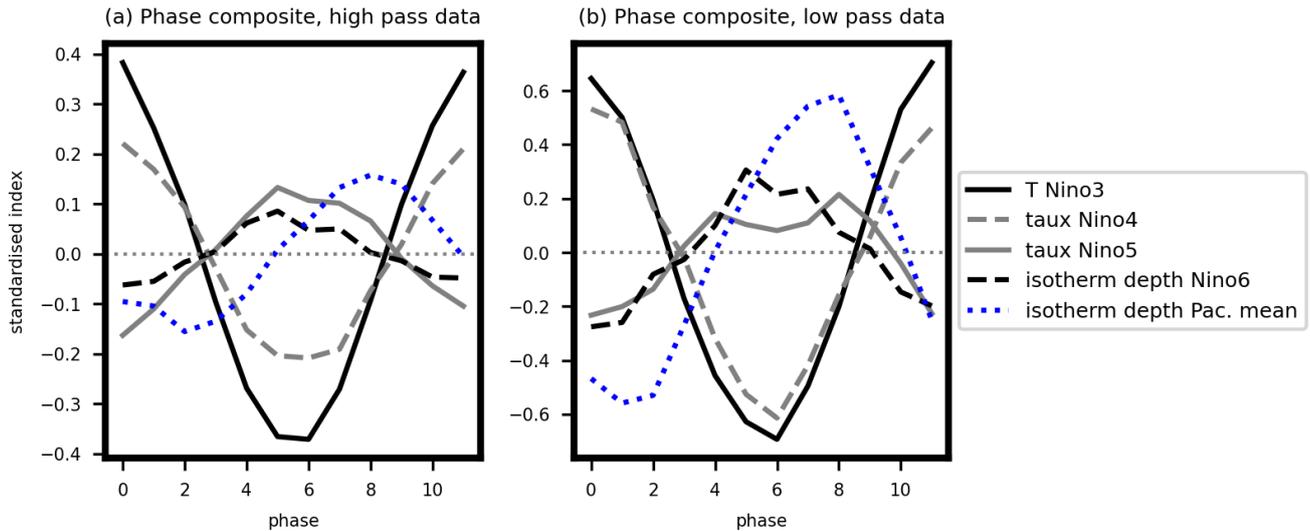

**Figure 2.** Latitude-longitude phase composite (phases 0 to 11 as labelled) of IMF13: shading for SSTs, contours for thermocline depth (contour interval is the same as in the colourbar with solid contours representing positive values, dashed contours negative values), and arrows for  $\tau_x$  (the scale is shown in the bottom left corner of panels for phases 10,11). All data is standardised and all fields were composited based on the phase of the SST (Niño3) index.

Together the two figures (Figs. 2, 3a,c) suggest the following sequence of events: (i) during La Niña (phases 5-7) we have 335 negative SST anomalies and shallower thermocline in Niño3 region, stronger easterly wind stress in Niño4 region, and deeper

**Figure 3.** Phase composites of SST (Niño3) (black solid line), isotherm/thermocline depth (Niño6) (black dashed line), isotherm/thermocline depth (across tropical Pacific) (blue dotted line),  $\tau_x$  (Niño4) (grey dashed line),  $\tau_x$  (Niño5) (grey solid line). All fields are composited over the phases of SST (Niño3), such that they fit the phases in Fig. 2. (a) composites of IMF13 for data divided by the standard deviation of corresponding timeseries (e.g., IMF13 (thermocline)/ $\sigma$  (thermocline)); (b) composites of band-pass filtered (25-52.5 months) standardised timeseries; (c) as in (a) but IMF-timeseries are divided by IMF's standard deviation (e.g., IMF13 (thermocline)/ $\sigma$  (IMF13 of thermocline)); (d) composites of the fields from the conceptual oscillator timeseries (Eqs. (5)-(8)), divided by standard deviations of corresponding timeseries (similar to (c)).

thermocline in the western Pacific (including Niño6 region); (ii) as La Niña weakens (phases 8-10), the westerly wind stress in Niño5 region and thermocline depth averaged across the tropical Pacific peak, starting the El Niño cycle; (iii) SSTs warm, thermocline (Niño3) becomes deeper, wind stress (Niño4) becomes westerly, and thermocline in the western Pacific (including

**Figure 4.** As in Fig. 3b, but for (a) higher frequency (band-pass filter over 11-19 months) data and (b) lower frequency (band-pass filter over 50-112 months) data. Note that higher and lower frequency timescale bands were chosen based on timescale ranges of 11<sup>th</sup> and 14<sup>th</sup> IMFs, i.e., the IMFs with slightly smaller or larger (respectively) timescales than IMF12, IMF13.

Niño6 region) becomes shallower (phases 11,0,1); (iv) El Niño weakens (phases 2-4) and  $\tau_x$  (Niño5) becomes easterly as well as the thermocline across the Pacific becomes shallower, starting a La Niña event (phases 5-7); (v) the cycle repeats. Note that there are also wind stress changes in the far eastern tropical Pacific that generally oppose the ones in the Niño4 region (Fig. 2), but occur roughly at the same time and are thus not explicitly considered further.

The evolution described above is also seen in the band-pass (25-52.5 months; 2-4.5 years) filtered data (Fig. 3b). Note that the values in Fig. 3b are slightly larger than in Fig. 3a, because slightly different frequency ranges are ultimately represented in the two panels, but they remain qualitatively similar. Similar results can also be obtained for the 17-32 months band-passed data and IMF12 (e.g., Fig. S2 in supplement). However, at lower and higher frequencies the evolution is different with  $\tau_x$  (Niño5) closely following thermocline (Niño6) (Fig. 4a,b), whereas other variables remain similar across timescales (to  $\pm 1$  phase). This suggests a different behaviour of the high- and low-frequency tropical Pacific variability compared with the 1.5-4.5-year variability (IMF12,13) discussed here.

Since we observe clear relationships between the relevant variables (e.g., Fig. 2) that strongly resemble a unified oscillator of Wang (2001a) (see also Fig. 5 in Wang 2018), recharge-discharge oscillator (e.g., Burgers et al., 2005), and others, we now revisit the theory of ENSO dynamics using the relevant conceptual oscillator models.

## 3.2 Conceptual oscillator models of ENSO

### The Unified Oscillator

355 As mentioned in the introduction, there are several different conceptual oscillator models (e.g., Wang, 2018): (i) the delayed; (ii) the recharge-discharge; (iii) the advective-reflective; (iv) the Western Pacific; and (v) the unified oscillator. The latter encompasses all the previous oscillators, and can be described by four relatively simple equations (Wang, 2001a)

$$\frac{dT}{dt} = a\tau_1 - b_1\tau_1(t - \eta) + b_2\tau_2(t - \delta) - b_3\tau_1(t - \mu) - \varepsilon T^3 \quad (1)$$

$$\frac{dh}{dt} = -c\tau_1(t - \lambda) - R_h h \quad (2)$$

360  $\frac{d\tau_1}{dt} = dT - R_{\tau_1}\tau_1 \quad (3)$

$$\frac{d\tau_2}{dt} = eh - R_{\tau_2}\tau_2 \quad (4)$$

where  $T$  is SST in Niño3 region,  $h$  is thermocline depth in Niño6 region,  $\tau_1$  is  $\tau_x$  in Niño4 region,  $\tau_2$  is  $\tau_x$  in Niño5 region, the constants are:  $a = 1.5 \times 10^{-2} \text{ K m}^2 \text{ N}^{-1} \text{ yr}^{-1}$ ,  $b_1 = b_3 = 2.5 \times 10^2 \text{ K m}^2 \text{ N}^{-1} \text{ yr}^{-1}$ ,  $b_2 = 7.5 \times 10^2 \text{ K m}^2 \text{ N}^{-1} \text{ yr}^{-1}$ ,  $c = 1.5 \times 10^3 \text{ m}^3 \text{ N}^{-1} \text{ yr}^{-1}$ ,  $d = 3.6 \times 10^{-2} \text{ N m}^{-2} \text{ K}^{-1} \text{ yr}^{-1}$ ,  $e = 3 \times 10^{-3} \text{ N m}^{-3} \text{ yr}^{-1}$ , the damping coefficients are: 365  $\varepsilon = 1.2 \text{ K}^{-2} \text{ yr}^{-1}$ ,  $R_h = 5 \text{ yr}^{-1}$ ,  $R_{\tau_1} = R_{\tau_2} = 2 \text{ yr}^{-1}$ , and the delay times (lags) are:  $\eta = 150$  days,  $\delta = 30$  days,  $\lambda = 180$  days,  $\mu = 90$  days. The unified oscillator and all its special cases listed above have a timescale range between 2 and 5 years with the provided parameters.

Eqs. (1)-(4) represent different processes in the tropical Pacific (Wang, 2001a). Eq. (1) represents changes to the SSTs in the Niño3 region via: (i) positive Bjerknes feedback (first term on the right-hand-side (RHS)); (ii) negative feedback due to 370 Kelvin wave reflection at the western ocean boundary (second term on the RHS); (iii) negative feedback due to wind-forced Kelvin wave contribution in the equatorial western Pacific (third term on the RHS); (iv) negative feedback due to Rossby wave reflection at the eastern ocean boundary (fourth term on the RHS); and (v) cubic damping term that limits anomaly growth (last term on the RHS). Eq. (2) represents changes to the off-equatorial thermocline depth (Niño6 region) via the wind stress in the equatorial central Pacific (Niño4 region) (first term on the RHS) and linear damping (second term on the RHS). Eq. (3) 375 represents changes to the zonal wind stress ( $\tau_x$ ) in the equatorial central Pacific (Niño4 region) via SSTs in equatorial eastern Pacific (Niño3 region) (first term on the RHS) and linear damping (second term on the RHS). Finally, Eq. (4) represents changes to the zonal wind stress in the equatorial western Pacific (Niño5 region) via off-equatorial western Pacific thermocline depth (Niño6 region; first term on the RHS) and linear damping (second term on the RHS).

However, the results from section 3.1 suggest that the average evolution on 2-3 year (average) timescale is different from the 380 unified model and many other oscillator models discussed in Wang (2001a). In section 3.1 we have established that  $\tau_x$  (Niño4) closely follows SST (Niño3) (Fig. 3a,b,c), i.e., they co-vary. Similarly, Fig. 3a,b,c suggests that thermocline depth (Niño6) is ‘anticorrelated’ with SST (Niño3) and  $\tau_x$  (Niño4). Therefore, we now assume: (i)  $\tau_1 \propto T$  by setting  $d\tau_1/dt = 0$ , yielding  $\tau_1 = dT/R_{\tau_1}$ , i.e., we replace  $\tau_1$  by  $dT/R_{\tau_1}$  everywhere; (ii)  $h \propto -\tau_1, -T$  by setting  $dh/dt = 0$ , yielding  $h = -c\tau_1/R_h = -cdT/R_h R_{\tau_1}$ , i.e., we replace  $h$  by  $-cdT/R_h R_{\tau_1}$  everywhere; (iii) assume that the wave reflections at both eastern and

385 western ocean boundaries are not necessary for this oscillator (typically assumed for the Western Pacific oscillator) by setting  $b_1 = b_3 = 0$ ; (iv) for simplicity set  $\lambda = \eta = \mu = 0$ , and keep the other parameters the same. This yields a modified unified oscillator

$$\frac{dT}{dt} = a \frac{d}{R_{\tau_1}} T + b_2 \tau_2 (t - \delta) - \varepsilon T^3 \quad (5)$$

$$h = -\frac{cd}{R_h R_{\tau_1}} T \quad (6)$$

390  $\tau_1 = \frac{d}{R_{\tau_1}} T \quad (7)$

$$\frac{d\tau_2}{dt} = -e \frac{cd}{R_h R_{\tau_1}} T - R_{\tau_2} \tau_2. \quad (8)$$

Fig. 3d shows a phase composite over the synthetic timeseries generated by solving equations (5)-(8) numerically with a first order Euler method (other more complex methods yield the same results). The phase composite (lines are the same as in Fig. 3c, except for exclusion of the blue dotted line) clearly demonstrates that the lags between  $\tau_x$  (Niño5), thermocline (Niño6), and SST (Niño3) or  $\tau_x$  (Niño4) are consistent with observations (Fig. 3c). The timescale of this oscillator (using the same parameters as above) is  $\sim 3$  years, i.e., similar to IMF13 timescale. The timescale was assessed via the timelapse between different peaks in the timeseries that the oscillator model of Eqs. (5)-(8) yields.

The parameters in Eqs. (5)-(8) can theoretically be adjusted (e.g., to change timescale) until the oscillatory behaviour breaks (or the ‘system’ becomes unphysical), which is true also for the unified oscillator in Eqs. (1)-(4). Note that if  $\delta = 0$  this oscillator and its timescale remain similar (not shown). This is consistent with Weisberg and Wang (1997), who noted that Western Pacific oscillator remains qualitatively similar when all lags are set to 0. We will refer to Eqs. (5)-(8) as a *simplified West-Pacific (SWP) Oscillator* from hereon, since this model is somewhat similar to the Western Pacific oscillator developed by Weisberg and Wang (1997), except for the conditions  $\tau_1 = dT/R_{\tau_1}$  and  $h = -cdT/R_h R_{\tau_1}$ . We view the SWP Oscillator model as another special case of the unified oscillator.

405 As mentioned above, the Western Pacific oscillator can be captured by Eqs. (1)-(4) by setting  $b_1 = b_3 = 0$ , typically describing the following series of events (e.g., Wang, 2001b, their Fig. 2). During the warm phase of ENSO there is (*atmospheric*) condensation heating in the equatorial central Pacific (Niño4) (e.g., Deser and Wallace, 1990) that induces a pair of low pressure anomalies in the off-equatorial central Pacific region. This drives the westerly wind anomalies in the central Pacific (Gill 1980; see also yellow arrows in phases 10,11,1,2 in Fig. 2). The wind stress (Niño4) then leads to deeper thermocline and warmer SSTs in Niño3 region (solid contours and red colours in phases 10,11,1,2 in Fig. 2), i.e., a positive (Bjerknes) feedback further amplifies the signal (reflected in Eqs. (1) [first term], (3)).

415 However, these off-equatorial low pressure anomalies act to raise the off-equatorial thermocline via Ekman pumping (evident through dashed contours in phases 10,11,1,2 in Fig. 2) (e.g., Wang, 2001b). This brings colder waters to the off-equatorial ocean surface, cooling the SSTs in Niño6 region (captured in Eq. (2) via thermocline impacts on SSTs), and introduces a pair of off-equatorial high pressure anomalies in the western Pacific. These then induce easterlies in equatorial western Pacific (Niño5) (yellow arrows in phase 3 in Fig. 2; also reflected in Eq. (4)), which can ultimately cause upwelling of the cold waters. This

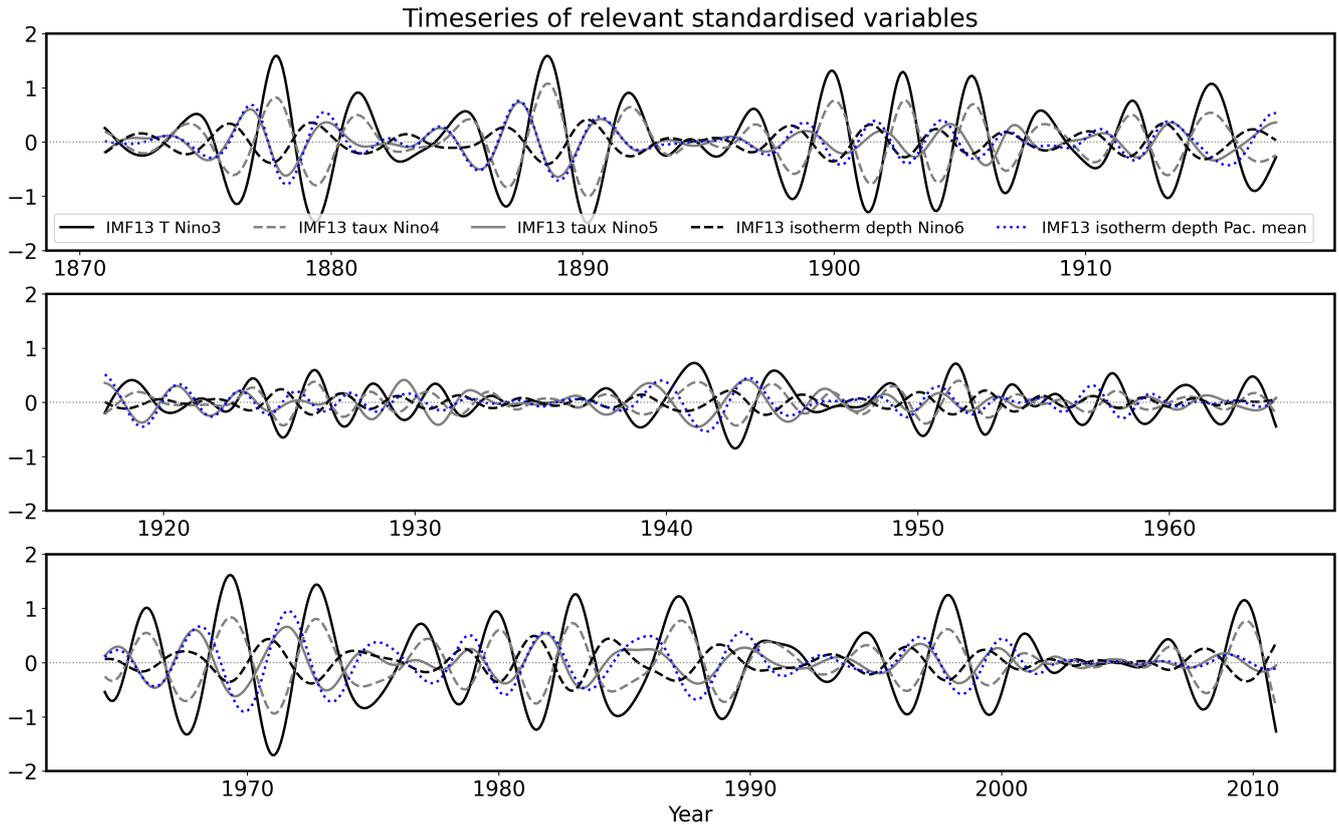

upwelling then extends further eastward (dashed contours and blue colours in phases 3-8 in Fig. 2; also reflected in Eq. (1) - third term on the RHS) with Kelvin wave propagation (reflected in delay time  $\delta$ ), leading to a negative phase of ENSO, La Niña, and the cycle repeats.

420 What is different in the SWP Oscillator compared with, e.g., the West-Pacific oscillator? The relationship between  $h$ ,  $T$  and  $\tau_1$  in Eqs. (6), (7) suggests that on 17-52.5 months timescale the atmosphere over the central-eastern Pacific is co-varying (is in a ‘steady state’) with the underlying ocean in SWP Oscillator (cf., Wang, 2001a), and that eastern (co-varying with SSTs (Niño3)) and western Pacific thermocline depth anomalies also co-vary, but are anti-correlated, unlike in the West-Pacific oscillator. However, the western Pacific wind stress (Niño5) keeps an out-of-phase relationship with the SSTs (Niño3),  
 425 suggesting an important role of the western Pacific in ENSO variability on 17-52.5 months timescale. Note that this analysis does not necessarily imply causality, and that other processes are likely needed to ultimately cause an ENSO event (e.g., related to a delayed oscillator or recharge-discharge oscillator discussed below). This is because the western Pacific winds are weak compared to the central Pacific winds. However, the western Pacific winds are important for forcing eastward-propagating Kelvin waves, which can represent additional feedback for ENSO growth/decay (e.g., Wang, 2018). The western Pacific wind  
 430 anomalies could also reflect ‘state-dependent westerly wind bursts’ in the western Pacific (Lopez et al., 2013; Lopez and Kirtman, 2014; Timmermann et al., 2018) that are important for the onset of ENSO events.

Fig. 3 and Eqs. (5)-(8) describe an average evolution of the parameters  $(\tau_1, \tau_2, T, h)$ , but not all individual events have this exact behaviour – partly reflected in the reduced amplitudes of  $\tau_x$  and thermocline in Fig. 3a compared with the SST amplitude. The full timeseries of these parameters (Fig. 5) show that the relationship from Fig. 3a,b,c occurs often in the analysed period,  
 435 especially for strong events. However, for weak events (middle panel in Fig. 5) the relationship is harder to establish – every event seems to be slightly different. This is somewhat consistent with Crespo et al. (2022), who noted that the dynamics of ENSO was different prior to 1970 relative to after 1970 with a dominant recharge-discharge oscillator in the latter period. Note that below we show that there is likely a relationship between the SWP and the recharge-discharge oscillators.

As seen in section 3.1, the dynamics on timescales of about 2-3 years (with a range of 1.5-4.5 years; Fig. 3) is different from  
 440 the higher and lower frequencies (Fig. 4). Thus, the variables that are important for the SWP Oscillator are not necessarily important for the variability on shorter/longer timescales. On shorter/longer timescales, one can make the assumption  $\tau_2 \propto h$ , since  $\tau_x$  (Niño5) closely follows thermocline (Niño6). Additionally, Fig. 4 shows that  $\tau_1, T \propto -\tau_2, -h$ , i.e., these quantities are anticorrelated. This correlation suggests that a unified model on shorter/longer timescales may be simplified to a delayed oscillator (involving  $T$  alone). Note that we discuss below the recharge-discharge oscillator of Burgers et al. (2005), which is  
 445 also present on those timescales (blue dotted lines in Fig. 4).

Some of the results here are consistent with Graham et al. (2015), who considered 12-month low-pass filtered data to assess the conceptual unified model of Wang (2001a). They provided several suggestions to improve the unified model of Wang (2001a), e.g., to remove the tendency terms for both wind stress terms (in Eqs. (3), (4)). As mentioned above, Fig. 4 suggests that such approximation would likely yield better results than the original unified oscillator model. However, this would only  
 450 work in the high- and low-frequency ranges discussed here (Fig. 4), but not on timescales in between, i.e., timescales of about 1.5-4.5 years (Fig. 3). On those intermediate timescales, the SWP Oscillator presented here should be used instead. This means

**Figure 5.** IMF13's standardised timeseries of SST (Niño3) (black solid line), thermocline depth (Niño6) (black dashed line), thermocline depth (across tropical Pacific) (blue dotted line),  $\tau_x$  (Niño4) (grey dashed line),  $\tau_x$  (Niño5) (grey solid line).

that on these intermediate timescales the tendency of the wind stress in the Niño5 region should be kept, but the one in the Niño4 region may be omitted.

Graham et al. (2015) also provided other suggestions, like adding a stochastic forcing term to wind stress equations (not attempted here for simplicity), and they also suggested using the thermocline depth in the Western Pacific averaged over a region that lies on the equator, rather than off-Equator. From Fig. 2 we can see that this would likely yield similar results as thermocline depth averaged over the Niño6 region (to  $\pm 1$  phase). They also suggested that a delayed oscillator is generally sufficient for describing ENSO variability, which may be true but only for shorter/longer timescales (Fig. 4) that are not necessarily quasi-periodic.

#### 460 **The Recharge-Discharge Oscillator**

The SWP Oscillator is based on Wang (2001a), which uses West-Pacific wind stress and off-equatorial thermocline depth as part of the overall ENSO oscillator. However, Burgers et al. (2005) suggested using only the Pacific mean thermocline depth

and SSTs (Niño3), which led to the (simplest) recharge-discharge oscillator

$$\frac{d}{dt} \begin{pmatrix} T \\ h_{\text{Pac}} \end{pmatrix} = \begin{pmatrix} -2\gamma & \omega_0 \\ -\omega_0 & 0 \end{pmatrix} \begin{pmatrix} T \\ h_{\text{Pac}} \end{pmatrix} \quad (9)$$

465 where  $T$  is SST (Niño3),  $h_{\text{Pac}}$  is the thermocline depth averaged across the tropical Pacific,  $\gamma^{-1} = 24_{-11}^{+22}$  months is the damping timescale, and the period of this oscillator is  $2\pi\omega^{-1} = 37_{-4}^{+8}$  months ( $\approx 2\pi\omega_0^{-1}$ ), with  $\omega^2 = \omega_0^2 - \gamma^2$ . The sub- and super-scripts in the period and damping timescale provide their 95% confidence levels. Note that the Burgers et al. (2005) model is based on the model developed by Jin (1997a, b). The recharge-discharge oscillator (e.g., Wang, 2001b) is related to Sverdrup transport (Sverdrup, 1947), which is associated with both zonal wind stress in the central Pacific (i.e., off-equatorial wind-stress curl) and SSTs in the eastern Pacific. This is driving the recharge-discharge of the equatorial heat content that ultimately gives rise to oscillations.

Fig. 3a,b,c clearly demonstrates that SST (Niño3; black solid line) and thermocline depth averaged across the tropical Pacific (blue dotted line) are  $\sim 90^\circ$  out of phase, consistent with the recharge-discharge oscillator of Jin (1997a, b); Burgers et al. (2005). We can also see (Fig. 3a,b,c) that  $\tau_x$  (Niño5) (grey solid line) shows variability consistent with (proportional to) the thermocline depth averaged across the tropical Pacific (blue dotted line), i.e., one may assume  $\tau_2 \propto h_{\text{Pac}}$  (in fact, their standardised values are essentially equal for IMF13). As with the SWP Oscillator, the relationship between the relevant variables in the recharge-discharge oscillator on the 2-3 year timescale largely remains the same over time (Fig. 5).

Wang (2001a) suggested that a recharge-discharge oscillator can be derived from the unified model by assuming  $\tau_2 \propto h$ . However, Fig. 3 suggests that on 2-3 year timescale the Pacific mean thermocline ( $h_{\text{Pac}}$ ) and wind stress in the western Pacific ( $\tau_2$ ) co-vary, thus the approximation should be  $\tau_2 \propto h_{\text{Pac}}$  to retrieve the Burgers et al. (2005) model. The recharge-discharge and SWP oscillators are thus likely related on 2-3-year timescale, which could suggest a role of western Pacific wind-forced Kelvin waves in recharge-discharge process (and vice versa). Thus, another way of looking at the two oscillators is to combine them, e.g.: (i) by using the recharge-discharge oscillator (Eq. 9) or SWP Oscillator (Eqs. 5-8) and setting  $\tau_2 = \alpha_1 h_{\text{Pac}}$  or  $h_{\text{Pac}} = \alpha_2 \tau_2$  (with  $\alpha_{1,2}$  a constant); (ii) by replacing  $h$  in the unified model with  $h_{\text{Pac}}$  and re-tuning the parameters of the model; or (iii) setting  $\tau$  during the recharge/discharge process to a non-zero value  $\tau_2$  (see, e.g., Fig. 1b,d in Jin 1997a), i.e., potentially re-tuning the recharge-discharge oscillator. It may also be necessary to reassess the relative importance of different variables in the oscillator models.

The relationship between the SSTs (Niño3) and the Pacific mean thermocline depth remains the same at lower and higher frequencies (see black solid and blue dotted lines in Fig. 4), suggesting that the recharge-discharge oscillator (Jin, 1997a, b; Burgers et al., 2005) is present on all timescales considered here. This makes the relationship between the SWP and recharge-discharge oscillators less clear on these longer/shorter timescales (Fig. 4). This suggests that the relationship between the two models is non-trivial, and can depend on the timescale (Figs. 3, 4). However, this also suggests that the unified oscillator captures different dynamics on different timescales, and that this is likely related to different behaviour in the western Pacific on different timescales, since  $\tau_x$  (Niño5)'s relationship with other variables changes substantially. These relationships should be explored further in the future.

Overall, in this section we have identified a SWP Oscillator in the frequency range 1.5-4.5 years in observations/reanalyses (Fig. 3c) and through a conceptual oscillator model (equations (5)-(8); Fig. 3d) by modifying the unified oscillator model (equations (1)-(4); Wang 2001a). At lower and higher frequencies we have found a different behaviour, likely related to different dynamical processes in the western Pacific on those timescales. Note, however, that a quasi-periodic behaviour in observations on shorter/longer timescales has not been detected. We have also found a recharge-discharge oscillator (Jin, 1997a; Burgers et al., 2005) on *all* timescales, suggesting similar dynamical processes in the eastern Pacific on all timescales considered, and a complex relationship with the unified model (Wang, 2001a) and SWP Oscillator. This suggests that a reassessment of the conceptual oscillator models and their links across timescales may be necessary (left for future work). Additionally, this section has confirmed that MEMD can extract physical modes of variability from the data.

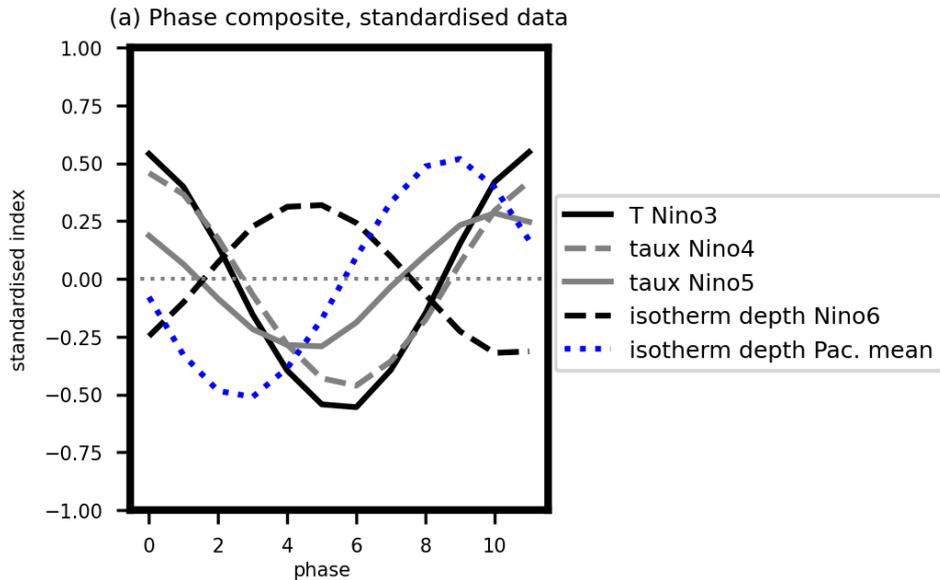

#### 505 4 Further implications of understanding ENSO's quasi-periodic variability

The previous section established that the unified model (e.g., Wang, 2001a) can be simplified to SWP Oscillator model in observations on quasi-periodic timescales and that its relationship with recharge-discharge oscillator (e.g., Burgers et al., 2005) is complex. Here, we first discuss the representation of the SWP and recharge-discharge oscillators in a climate model (section 4.1). Then, we test ENSO predictability on quasi-periodic timescales using a simple statistical model (section 4.2, Appendix C).

##### 4.1 Model evaluation

Since the modes extracted via MEMD are physical and the significant modes are quasi-periodic (via a red noise test), we can now repeat the analysis in a climate model. Here, we use the NorCPM1 historical simulation (first ensemble member; the other ensemble members show qualitatively similar results) to test the ENSO dynamics in different frequency bands (similar to Fig. 3). The MEMD analysis yields two significant (quasi-periodic) modes also in the model: IMF14 with a timescale of 27 months (range: 22 - 35 months), and IMF15 with a timescale of 38 months (range: 27 - 54 months). As in the observations, the two modes show similar behaviour (see Figs. S3-S5 in supplement) and have a similar range (22-54 months) of quasi-periodic behaviour as observations (17-52.5 months).

Fig. 6 shows the model's IMF15 phase composites, a figure equivalent to observations' Fig. 3a (note that as in observations, also here the same band pass filter yields similar results to an IMF). For full temporal evolution (model equivalent of Fig. 5) see Fig. S6 in the supplement. While the recharge-discharge oscillator (e.g., Burgers et al., 2005) is well represented in the model (black solid line for SST (Niño3) and blue dotted line for the tropical Pacific mean thermocline depth), the SWP Oscillator (other lines and black solid line) shows slightly different behaviour compared with observations. This is especially evident in the  $\tau_x$  (Niño5; grey solid line), which peaks just before the SST (Niño3; black solid line), leading it by  $\sim 1$  phase (Fig. 6), whereas in observations (Fig. 3a) it peaks well before the SST (Niño3), leading it by  $\sim 3$  phases. At the same time,  $\tau_x$  (Niño5; grey solid line) is anticorrelated with thermocline depth (Niño6; black dashed line), which is different from observations where thermocline depth (Niño6) was anticorrelated with SST (Niño3) and  $\tau_x$  (Niño4).

**Figure 6.** As in Fig. 3a, but for the corresponding IMF15 fields in the NorCPM1 (ensemble member 1).

This suggests an issue in the model’s representation of the ENSO dynamics on 2-3 year timescale, which is especially pronounced in the western Pacific (SWP Oscillator), where both  $\tau_x$  (Niño5) and thermocline depth (Niño6) tend to have phase-lag relationship with SST (Niño3) slightly incorrectly represented relative to observations (Figs. 6, 3a). On the other hand, the recharge-discharge mechanism, which is stronger in the eastern Pacific, is more correctly represented, i.e., phase-lag relationship between thermocline depth (Pacific mean) and SSTs (Niño3) is similar to observations. The  $\tau_x$  (Niño4) shows similar evolution as in the observations, but its strength is stronger in the model (compare grey dashed lines in Figs. 3a, 6), suggesting a stronger feedback to the SST (Niño3) or less varied dynamical processes. Consistently, there is also a stronger relation of the SST (Niño3) to the tropical Pacific mean thermocline depth (larger amplitude relative to the SSTs compared with observations; compare blue dotted lines in Figs. 3a, 6; see also large values in spatial composites of Fig. S4), likely suggesting a stronger (more dominant) recharge-discharge oscillator in the model compared with observations.

The strong East-Pacific thermocline-SST feedback in the model was also identified as a general model bias in Chen et al. (2021), who also identified model biases in the western Pacific (e.g., SST anomalies during ENSO events extending too far west; see also Figs. S3,S4). These are likely responsible for different model behaviour in the western Pacific compared with observations. We also found differences at low and high frequencies between the model and the observations in the unified oscillator, further suggesting potential issues with the dynamics of ENSO on different timescales in the model.

This analysis suggests that timeseries analysis methods (e.g., MEMD) may be used to evaluate models. Here, such analysis confirms that the analysed model has correct periodic behaviour (perhaps too periodic), however it may be struggling with the exact physics that lead to the onset of ENSO (or ENSO diversity), which should be considered for future model improvements (see also Guilyardi et al. 2020; Planton et al. 2021). Nonetheless, since (i) the recharge-discharge process is well represented

in the model; (ii) the model exhibits quasi-periodic behaviour; and (iii) SST-variability alone could be sufficient for describing/predicting ENSO (see section 4.2; Graham et al. 2015) – the NorCPM1 (prediction system) should be able to predict ENSO, especially on timescales  $\sim 2-4$  years (left for future work).

## 550 4.2 Prediction

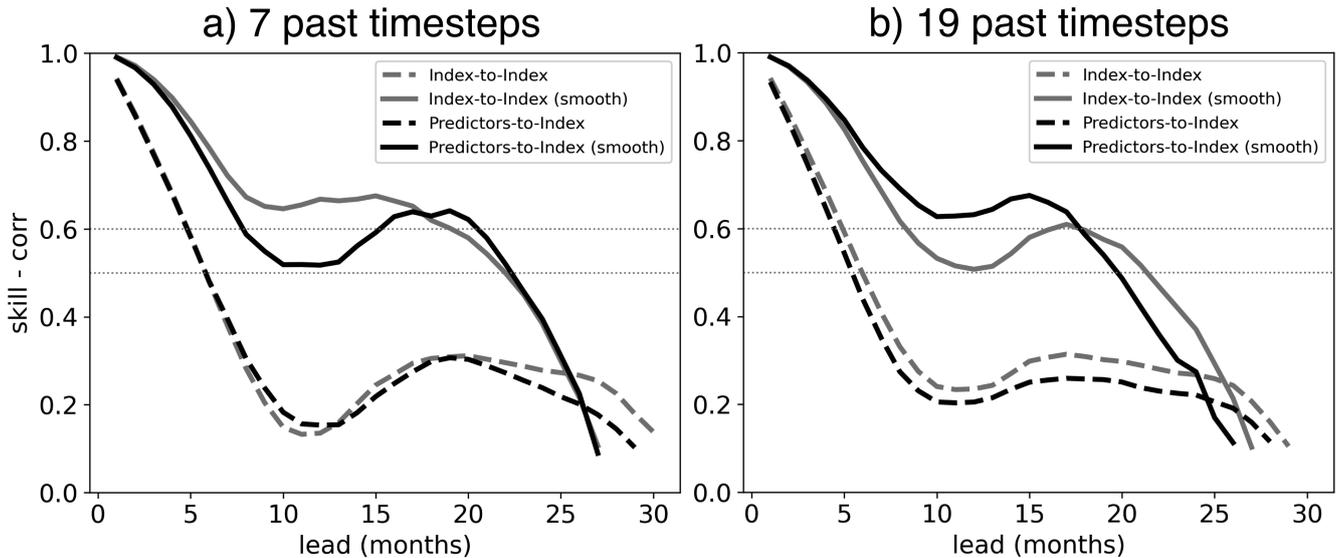

While a better understanding of the quasi-periodic variability (e.g., in ENSO) can help climate model improvements and thus ultimately their prediction skill, it can also help identification of timescale-windows in which predictions (e.g., of ENSO) work well. The latter means that quasi-periodic signal of ENSO (as identified above) may be predictable far in advance, even though full ENSO prediction is more challenging. This is what we test in this section.

555 To do this, we use a relatively simple multi-linear regression model (for details see Appendix C; cf., Omrani et al. 2022) with three (input) timeseries: SST (Niño3),  $\tau_x$  (Niño5), and thermocline depth (Niño6) to predict the SST (Niño3). We included thermocline depth (Niño6) as a predictor as this improved the results compared with using just SST (Niño3) and  $\tau_x$  (Niño5) as predictors, which are the two main quantities in the SWP Oscillator (Eqs. (5) - (8)). On the other hand, we do not use  $\tau_x$  (Niño4) as it is clear from Figs. 3, 4 that it is somewhat redundant (has the same evolution as the SST (Niño3)), and including  
560 it actually weakens predictability (not shown). Similarly, predictions from tropical Pacific mean thermocline depth are not considered here as they did not improve predictions (not shown).

Before inputting timeseries into the prediction model (for details see Appendix C) we lag the data so that all timeseries maximise at ‘lag 0’ and we additionally use up to 19 past timesteps of each timeseries to improve predictions. The prediction model is constructed separately for each lead time and is repeated for all months within the 1871-2010 period (except for the  
565 timesteps used for lagging the data). We use 60% of data for training and 40% of the data for testing.

The skill of the prediction is assessed using the correlation between the true SST (Niño3) and its prediction in the testing dataset. This is done on raw data (i.e., unsmoothed) and on smoothed data using 25-52.5 months band-pass, where the SST (Niño3) quasi-periodic behaviour is strongly significant in observations (i.e., IMF13 timescale band). Note that the prediction model is always applied on raw data, and the prediction itself is later smoothed by using the band-pass filter, before comput-  
570 ing the correlations. This is done because any smoothing of the data before inputting it into the prediction model can yield misleading (over-confident) results. An extension to 17-52.5 months band (used above) reduces the skill significantly (perhaps because IMF12 is marginally significant; e.g., Fig. S2) and is hence not pursued further (not shown).

Fig. 7 shows SST (Niño3) prediction skill for 30 months lead time using (a) 7 months of past timesteps within predictors, and (b) 19 months of past timesteps within predictors for predictions from SST (Niño3) alone (grey lines), and predictions  
575 from all predictors (black lines). Dashed lines represent the raw prediction skill, and solid lines represent prediction skill of smoothed data (25-52.5 months band-pass). This reveals that there is extended prediction skill in the smoothed data to  $\sim 18$  months lead time (skill score over 0.6) compared with raw prediction skill ( $\sim 5$  months) in the simple statistical model. This is consistent with the oscillatory behaviour in that timescale-band (identified in section 3). Note that smoothing predictions over a narrower timescale band (e.g., 26.5-51 months) before computing correlations can yield slightly better results, i.e., longer  
580 predictability range (not shown).

**Figure 7.** Correlation skill score of a multi-linear regression model for predicting SST (Niño3) from (a) 7 past timesteps (in months), and (b) 19 past timesteps (in months). The dashed lines are for raw predictions (without smoothing), and solid lines are for a (smoothed) band-pass filtered prediction (25-52.5 months). Note that we smooth the raw prediction to get the smooth-prediction skill score. The grey lines are for a prediction from SST (Niño3) alone, whereas black lines are for prediction from SST (Niño3),  $\tau_x$  (Niño5) and thermocline depth (Niño6). For further details see the text.

Fig. 7a reveals that we can get a good prediction of SST (Niño3) from SST (Niño3) alone by using 7 past timesteps (months), which can be slightly extended by a month or two when all predictors are considered (black solid line crosses the 0.6-skill-score line at a slightly longer lead time beyond 18 months). By using 19 past timesteps (months) (Fig. 7b), we can improve raw predictions (dashed lines) for lead times 10-15 months, and the skill-score of smoothed predictions using all predictors (black solid line) improves relative to Fig. 7a. However, the latter yields slightly worse skill-score than prediction of SST (Niño3) from SST (Niño3) alone with 7 past timesteps (Fig. 7a, grey solid line), i.e., it lasts  $\sim 1$  month lead-time less in Fig. 7b (black solid line) – until lead time  $\sim 17$  months. Note that root-mean-square error was not sensitive to the choice of predictors, hence it is not shown.

These results suggest that (linear) statistical predictions of ENSO can be well captured by SST (Niño3) alone, which is perhaps consistent with Graham et al. (2015), who suggested that a delayed oscillator is sufficient for describing ENSO. The importance of SST (Niño3) alone may also be due to other processes that can affect variables like thermocline depth (affected by, e.g., deep ocean dynamics) and wind stress (affected by, e.g., high-frequency atmospheric variability). These processes can then interfere with a (linear) statistical prediction of SSTs as it is computed from raw (unfiltered) data. Note that, here, we use a very simple linear statistical model and it is therefore hard to compare it directly to dynamical models or more sophisticated statistical models. Either way, this shows that ENSO’s quasi-periodic signal can be well predicted months in advance (even with a simple linear statistical model).

While this section suggests that there is indeed potential for very good predictability (for  $\sim 18$  months lead time) of ENSO on timescales 25-52.5 months, such predictability can only provide the sign of ENSO in this frequency band, and it can suggest a higher chance of positive or negative ENSO event, but it cannot provide the actual magnitude and prediction of the full ENSO event. A lot of work has been done on dynamical and statistical model predictions of ENSO, which can predict an ENSO event reasonably well up to 6 months ahead (sometimes more) from raw data (e.g., L'Heureux et al., 2020; Dijkstra et al., 2019). However, we show that such models might have a predictable (up to 1.5 years or more) component on timescales 25-52.5 months. This is also because models can simulate ENSO variability on this timescale well (as established in section 4.1). Perhaps ENSO events that can be predicted up to 2 years ahead (e.g., Chen et al., 2004; Park et al., 2018) have a stronger component of this  $\sim 2$ -4.5 year mode of variability (relative to red-noise variability of other modes).

Note that here we computed 'prediction' skill without any preconditioning or a selection of a season, therefore better skill scores may be obtained if the model is initialised in relevant seasons or based on certain precursors (left for future work).

## 5 Conclusions

In this study we have used observational and reanalysis products to study the variability in the tropical Pacific on interannual timescales (i.e., ENSO) and to revisit conceptual oscillator models of ENSO. To do this, we have used a recently developed method for identifying intrinsic variability of multivariate systems, the multivariate empirical mode decomposition (MEMD; Rehman and Mandic 2010). The method can objectively identify modes of variability on different timescales, i.e., it works as an objective band-pass filter. Then, a red noise significance test has been used to extract quasi-periodic modes of variability in the given data.

Here, we identified a clear quasi-periodic behaviour on a timescale of about 3 years (25-52.5 months; arguably also on extended timescale, 17-52.5 months, as discussed in previous sections). This timescale falls within the typical timescale range of ENSO, i.e., 2-8 years. While the ENSO quasi-periodic variability is a well-known feature, an identification (via MEMD) of a range of timescales of the quasi-periodic modes (e.g., 25-52.5 months) has led to a few interesting results.

By analysing composites of the thermocline depth, surface wind stress and the sea surface temperature (SST), we have shown that the  $\sim 3$ -year ENSO variability generally follows an oscillator model that is a subset of the unified oscillator (Wang, 2001a). We refer to this oscillator as a simplified West-Pacific (SWP) Oscillator, as it is slightly different from the other established oscillator models (i.e., the Western Pacific, delayed, advective-reflective, recharge-discharge oscillators). We have also identified the recharge-discharge oscillator of Burgers et al. (2005), which is described by a slightly different set of equations than the unified oscillator (i.e., uses Pacific mean thermocline depth instead of average over the Niño6 region). However, the recharge-discharge oscillator is present also on other timescales (not just on  $\sim 3$ -year timescale), unlike the SWP Oscillator. This suggests similar behaviour in the eastern Pacific on all timescales considered, but different behaviour in the western Pacific. This means that the relative role, phasing of and relationship between relevant variables in the tropical Pacific may change depending on the timescale. This may ultimately be important for interactions across scales that give rise to, e.g., an ENSO event, thus these relationships should be explored further in the future.

630 The SWP Oscillator (Eqs. (5)-(8)) resembles the Western Pacific Oscillator of Weisberg and Wang (1997), in that it keeps the evolution (tendency) of wind stress in the western Pacific (Niño5). However, based on the results from the reanalyses/observations (Fig. 3a,c) we assume that wind stress in the Niño4 region and thermocline depth in Niño6 region can be modelled through the SSTs in the Niño3 region (i.e., their tendencies can be omitted). This is because wind stress (Niño4) closely follows SST (Niño3) and thermocline depth (Niño6) is largely anticorrelated with SST (Niño3). This suggests co-  
635 variability of the atmosphere and ocean on interannual timescales in the central-eastern Pacific, but an out-of-phase relationship with the western Pacific coupled atmosphere-ocean processes, which are important for the generation of Kelvin waves at the western boundary. The latter provides additional feedbacks (e.g., Wang, 2018) for the variability in the eastern Pacific, suggesting that the western Pacific processes are important for ENSO variability. There might be an additional link to the ‘state-dependent westerly wind bursts’ that are important for ENSO onset (e.g., Lopez et al. 2013; Lopez and Kirtman 2014; Timmermann et al. 2018). However, since the amplitude of the western Pacific wind stress anomalies is generally small, it is likely that other processes are important as well – e.g., recharge-discharge of the heat content (see below).

The evolution of the SWP Oscillator on timescales of 17-52.5 months can be described in the following way (cf., Wang 2001b; Figs. 2, 3a,c):

- 645 1. warm phase of ENSO is associated with westerly winds in Niño4, warmer SSTs and deeper thermocline in Niño3 (phases 10,11,0 in Fig. 2);
2. this is associated with off-equatorial pair of low pressure anomalies in central Pacific, which can cause upwelling (via Ekman pumping) of the off-equatorial thermocline (becoming shallower), extending further west (incl. into the Niño6 region). This largely occurs together with the warmer SSTs in Niño3 (see evolution of dashed contours in phases 9-11,0-2 in Fig. 2);
- 650 3. the colder waters caused by upwelling of the thermocline in Niño6 lead to off-equatorial pair of high pressure anomalies in the western Pacific, which ultimately gives rise to easterlies in the western Pacific (Niño5) (e.g., yellow arrows in phase 3 in Fig. 2);
4. these easterlies can cause further upwelling of cold waters (shallower thermocline) in the equatorial western Pacific, which can then propagate as Kelvin waves further east (dashed contours in phases 0-4 in Fig. 2), bringing colder waters  
655 to the eastern Pacific and initiating the cold phase of ENSO (phases 4-6 in Fig. 2);
5. the cycle reverses and ultimately repeats.

The recharge-discharge oscillator of Burgers et al. (2005) is also present on the 17-52.5 months timescale throughout the analysed period (Fig. 5) and should be considered as part of (or alternative to) the SWP Oscillator (or vice versa). This is because the wind stress (Niño5) and the Pacific mean thermocline depth co-vary and are likely related to each other –  
660 their relationship should be explored further in the future. The evolution of the recharge-discharge oscillator (alone) can be summarised as follows (e.g., Burgers et al. 2005; Wang 2001b; Figs. 2, 3a,c): (i) during the warm phase of ENSO (phases

10,11,0 in Fig. 2) there is westerly wind stress in the central Pacific, warmer SSTs and deeper thermocline in the eastern Pacific; (ii) this is associated with divergent Sverdrup transport that ultimately drives discharge of the equatorial heat content, which leads to (climatological) upwelling of cold waters throughout the equatorial Pacific (phase 3 in Fig. 2); (iii) this initiates a cold phase of ENSO (phases 4-6 in Fig. 2), the cycle reverses and ultimately repeats.

Exploring the representation of ENSO's intrinsic variability in a climate model (NorCPM1) showed that the model has a similar quasi-periodic behaviour as the observations/reanalyses, with largely accurate (though too strong) recharge-discharge oscillator. However, SWP Oscillator is not really present, i.e., the dynamics is different, since wind stress (Niño5) peaks too late and thermocline depth (Niño6) peaks too early (Fig. 6). Similarly, the co-variability of the recharge-discharge and SWP oscillators is absent in the model. Therefore, we speculate that climate models (likely not just NorCPM1) may struggle with the relationship between the western and eastern Pacific coupled atmosphere-ocean processes.

By constructing a statistical prediction model, we have shown that SST variability on timescales of 25-52.5 months in the tropical Pacific may be predictable for up to 18 months in advance (Fig. 7). Also, given that NorCPM1 can reproduce the recharge-discharge oscillator well and that it exhibits periodic variability on timescales 2-4 years, we believe that it should be able to predict the variability on the 2-4 year timescale reasonably well – this is likely true for other models as well (left for future work). However, such prediction can only tell us that there is a higher chance of a certain ENSO event and it cannot yield a prediction of full ENSO amplitude, i.e., this remains challenging. This is because an ENSO event ultimately depends on variability on all timescales (and their interactions), thus its peak magnitude and timing will likely differ from the one identified on a specific (band-passed) timescale.

Therefore, a better understanding of ENSO variability on different timescales is important for a better representation of ENSO dynamics in the climate models. Additionally, it is important to understand ENSO impacts on different timescales both locally and remotely (teleconnections; e.g., Brönnimann, 2007; Fereday et al., 2008; Jiménez-Esteve and Domeisen, 2018; Jiménez-Esteve and Domeisen, 2020; Hardiman et al., 2019). The latter can be achieved through similar analysis as in this study, but including other fields and other (remote) regions in the analysis (e.g., mean-sea-level pressure in the Euro-Atlantic region). Also, future studies should involve an examination of sensitivity and causal links (not established here) between different variables (and their links across scales) within the Tropics and beyond (e.g., Runge et al., 2015; Jajcay et al., 2018; Jenney et al., 2019; Kretschmer et al., 2021), as well as dedicated model-experiments.

Overall, this study has analysed the variability in the tropical Pacific, identified a quasi-periodic mode of variability (on  $\sim 3$ -year timescale) and related its physics to the SWP and recharge-discharge oscillators, which are likely related to each other on this timescale. Variability on this timescale may be predictable far in advance, which calls for further investigations of the tropical Pacific variability and related teleconnections, their prediction, and for further model improvements (see also Chen et al., 2021; Lee et al., 2021).

*Code availability.* EMD and MEMD Python codes are available on Github (<https://github.com/laszukdawid/PyEMD>, <https://github.com/mariogrune/MEMD-Python->). Other scripts are available upon request.

## Appendix A: MEMD for 3-D fields

700 To find the intrinsic variability of our 3-D field, i.e.,  $\mathbf{A}'(t, y, x)$  mentioned in section 2.2, we first reduce dimensionality of our data by decomposing it using the singular value decomposition (SVD), which yields spatial patterns of our data (empirical orthogonal functions, EOFs) and corresponding timeseries (principal components, PCs). First, we multiply  $\mathbf{A}'$  by  $\sqrt{\cos\phi}$  (area weighting), divide by standard deviation ( $\sigma$ ) at each grid point (and for each variable separately, if relevant), and reshape  $\mathbf{A}'$  from  $(t, y, x)$  to  $(t, xy)$ . Then  $\mathbf{A}'$  can be expressed with a singular value decomposition as

$$705 \quad \sigma^{-1}(xy)\mathbf{A}'(t, xy) = \mathbf{U}\mathbf{\Sigma}\mathbf{V}^T \quad (\text{A1})$$

where  $\mathbf{U}$  and  $\mathbf{V}$  represent left and right singular vectors, i.e., the normalised PCs and EOFs,  $\mathbf{\Sigma} = \sqrt{(N-1)\mathbf{\Lambda}}$  is a diagonal matrix with square roots of variance explained of each mode (denoted  $\mathbf{\Lambda}$ , i.e., eigenvalues) along the diagonal,  $N$  is the number of spatial points, and superscript  $T$  denotes transpose. In order to keep the information of the variance explained of each mode within the data we define PCs as  $\mathbf{U}\mathbf{\Sigma}/\sqrt{N-1}$ , such that  $\sigma^{-1}(xy)\mathbf{A}'$  can be represented as a function of PCs and EOFs (recall

710 EOFs are in  $\mathbf{V}$ )

$$\sigma^{-1}(xy)\mathbf{A}'(t, xy) = \sqrt{N-1} \sum_{m=1}^{m=20} \text{EOF}(m, xy)\text{PC}(m, t) \quad (\text{A2})$$

where  $m$  corresponds to PC-number and is ordered according to the eigenvalues ( $m = 1$  for the largest eigenvalue). We retain only the leading 20 PCs for the analysis (they generally describe the majority of the variance in  $\mathbf{A}'$ ).

Now we can use the 20 PCs ( $\text{PC}(m, t)$ ) as input to MEMD algorithm (for details on algorithm itself see Rehman and Mandic  
 715 2010). This algorithm finds common timescales (i.e., Intrinsic Mode Functions, IMFs) within the 20 PCs and splits each PC into several IMFs (the number of IMFs is not predetermined). Thus, each PC can be represented as a sum of IMFs

$$\text{PC}(m, t) = \sum_{s=1}^{s=s_{max}} \text{IMF}(s, m, t) \quad (\text{A3})$$

where  $s$  corresponds to IMF-number and is ordered according to the timescale ( $s = 1$  for the shortest timescale,  $s_{max}$  for the longest timescale, which is usually a trend or a residual). Eq. (A3) shows that each PC is a superposition of different IMFs (see  
 720 also Table S2) and with it also a superposition of modes of variability in the selected field(s) with different timescales.

Each PC is associated with a spatial pattern ( $\text{EOF}(m, xy)$ ), which allows a reconstruction of the time-space  $(t, xy)$  structure/evolution for each IMF, yielding IMFs of initial dataset  $\mathbf{A}'$  (**IMFA**). We do this by multiplying PCs for each IMF with corresponding EOFs and summing over all 20 PCs/EOFs (similar to Eq. A2)

$$\sigma^{-1}(xy)\mathbf{IMFA}(s, t, yx) \simeq \sqrt{N-1} \sum_{m=1}^{m=20} \text{IMF}(s, m, t)\text{EOF}(m, xy). \quad (\text{A4})$$

725 Here note that to get **IMFA** in the units of the input field we must multiply it by the field's standard deviation as the input data for the SVD algorithm was standardised (Eq. A1). Again, **IMFAs** are ordered by timescale, i.e., **IMFA** 1 with the shortest timescale and **IMFA**<sub>*s<sub>max</sub>*</sub> with the longest timescale (trend). From here we can reconstruct **A'** by summing over all **IMFA**

$$\sigma^{-1}(xy)\mathbf{A}'(t, xy) \simeq \sum_{s=1}^{s=s_{max}} \mathbf{IMFA}(s, t, yx) \quad (\text{A5})$$

and ultimately one can also reshape **A'** from  $(t, xy)$  to  $(t, y, x)$ . The importance of each **IMFA** for **A'** can be assessed by computing variance explained of each **IMFA** or other significance methods. To find **IMFA** modes (and grid-points) that correspond to potentially oscillatory behaviour we must perform a red noise test (see Appendix B).

Note that from here on (and in the main text) **IMFAs** are referred to as **IMFs** for simplicity.

## Appendix B: Significance tests

Typically we can test if the modes (**IMFs**) are different from white or red noise, if we expect such distribution in our data. In the climate system, more often than not we expect the variables to behave as white or red noise. The **IMFs** that are significant (i.e., different from both red and white noise) are likely representing oscillations instead, which can suggest higher potential for predictability of processes that correspond to the timescale of the significant **IMF**. Thus, this distinction is very important in climate system science. Therefore, we discuss the white and red noise tests (for 1-D data, i.e., timeseries) below, whereas the robustness of **IMFs** and the significance tests are briefly mentioned where relevant in the main text.

740 Note that the white and red noise tests are performed on 1-D timeseries, hence EMD (univariate decomposition; see main text) is first used to test their performance. The multivariate data (via MEMD) is later analysed with the simplest and most relevant test.

### B1 White noise test

The white noise significance test has been derived by Wu and Huang (2004), who showed that the energy density function of  $s^{th}$  **IMF** ( $E_s$ ; i.e., average squared amplitude of the  $s^{th}$  **IMF**) is

$$E_s = \frac{1}{L} \sum_{j=1}^L [C_s(j)]^2, \quad (\text{B1})$$

where  $C_s(j)$  is the  $s^{th}$  **IMF** at time-step  $j$  ( $j = 1, \dots, L$ ), and  $L$  is the length of the timeseries. Wu and Huang (2004) further showed that the total energy density of the  $s^{th}$  **IMF** can then be expressed as

$$LE_s = \int S(\nu)_s d\nu \quad (\text{B2})$$

750 where  $\nu$  is frequency, and  $S(\nu)_s$  is the power spectrum of the  $s^{th}$  **IMF**. From this they showed that for white noise

$$\ln E_s \approx -\ln T_s \quad (\text{B3})$$

where  $T_s$  is the average period of the  $s^{th}$  IMF.

Note that frequency (and thus also period) of each IMF is computed using Hilbert transform by first generating an analytical signal (e.g., Huang et al., 1998)

$$755 \quad Z(t) = X(t) + iY(t) = |Z(t)|e^{i\theta(t)} \quad (B4)$$

where  $X(t)$  is our IMF timeseries,  $Y(t)$  is its Hilbert transform,  $Z(t)$  is the analytical signal, and  $\theta(t) = \arctan(Y(t)/X(t))$  is instantaneous phase. Instantaneous frequency can then be computed by taking a time-derivative of the phase, i.e.,  $\nu = d\theta(t)/dt/2\pi$ , and the average frequency of each IMF is computed by averaging instantaneous frequency in time (note that period =  $1/\nu$ , i.e.,  $T_s$ ).

760 The relationship between the logarithms of energy density and average period of the IMFs (Eq. B3) is then used in Fig. B1a (black solid line) to test whether an IMF (using EMD decomposition of Niño3 index; blue dots in Fig. B1a; see also section 2.2) is different from white noise or not. The mode is significant with respect to white noise if it exceeds one-tailed 95<sup>th</sup> percentile threshold (denoted by black dotted line). The percentile range serves as a significance test, i.e., if IMFs from our data are above, e.g., 95<sup>th</sup> percentile they are significant at 95<sup>th</sup> percentile level. The percentile range can be expressed analytically as (Wu and  
765 Huang, 2004)

$$\ln E_s = -\ln T_s \pm p\sqrt{\frac{2}{L}} \exp(\ln T_s/2) \quad (B5)$$

where  $p$  denotes a threshold ( $p = 1.645$  for one-tailed 95<sup>th</sup> percentile). Note that typically the number of degrees of freedom for white noise data is expected to be equal to the total energy density of the  $s^{th}$  IMF (i.e.,  $LE_s$ ; Wu and Huang 2004).

Blue dots in Fig. B1 are (in general) constructed the following way. First, we obtain IMFs via either EMD (Fig. B1a,b) or  
770 MEMD (Fig. B1c,d) analysis (for details see section 2.2 and Appendix A). Then, we compute average energy density (Eq. B1) from timeseries of each IMF, and average period of each IMF (for periods of IMFs from MEMD analysis see Tables S1, S2) using Hilbert transform (see text under Eq. B4). Then we obtain a natural logarithm of both average amplitude and average period of each IMF and plot them in Fig. B1 as  $\log_e(\text{period})$  vs.  $\log_e(\text{amplitude})$  of each IMF as a scatter plot. Thus, in Fig. B1 each blue dot represents amplitude and frequency of each IMF that we have identified within our timeseries/data. IMFs are  
775 ordered by frequency along the x-axis, i.e. left-most blue dot is IMF1 and right-most blue dot is trend (last IMF). Note that all dots and lines in Fig. B1 represent logarithmic values of period/energy-density.

Alternatively, we can test whether the input data is different from white noise by constructing multiple ( $I$ ) realisations of synthetic white noise timeseries  $w_i$  ( $i^{th}$  random normally distributed timeseries with standard deviation  $\sigma$  of 1). Then we can compute its IMFs via EMD (section 2.2) and we can repeat the process  $I$ -times. Employing Eq. B1 on these IMFs yields  
780 scattered grey dots in Fig. B1a (constructed in the same way as blue dots), where their mean and 5<sup>th</sup>-95<sup>th</sup> percentile are shown as grey solid and dotted lines, respectively.

A comparison with the IMFs from the input data (Niño3 index; blue dots in Fig. B1a) reveals that many IMFs lie outside the white noise range and that overall the data (blue dots) distribution does not resemble the white noise (grey dots) distribution (not noted in Wu and Huang 2004). This suggests that a white noise test for such data is not a good test. Indeed, atmosphere-

785 ocean coupled systems, such as ENSO, can often be represented as a red noise process (e.g., Hasselmann 1976; Frankignoul and Hasselmann 1977), thus we now turn to a similar test, but for data distributed as red noise.

## B2 Red noise test

### B2.1 Synthetic red noise data

To test if our data (e.g., Niño3 index) is purely red noise or it has inherent oscillations that we can identify through the (M)EMD analysis, we generate  $I$ -realisations of synthetic red noise timeseries  $x$  (AR(1) process) as (e.g., Gilman et al. 1963)

$$x_{i,j+1} = rx_{i,j} + \sqrt{1-r^2} w_{i,j+1} \quad (\text{B6})$$

where  $r$  is lag-1 auto-correlation from our data (e.g., Niño3 index),  $w$  is white noise (as in Appendix B1),  $i$  runs over  $I$  realisations of synthetic red noise data, and  $j$  ( $j > 1$  and  $j \leq L$ ; with  $L$  length of our data, e.g., the length of Niño3 record) is an index that runs over the time-steps (one time step is one time unit, e.g., 1 month). For  $j = 1$  (the first time-step) we set

$$x_{i,1} = w_{i,1}.$$

Once we obtain the red noise timeseries  $x_i$  we can compute its IMFs via EMD (section 2.2) and we can repeat the process  $I$ -times (as for the white noise; Appendix B1). This yields the pink scattered dots in Fig. B1b. The mean over  $I$  cases for each IMF (frequency band) is shown by pink solid line and the (one-tailed) 95<sup>th</sup> percentile across the  $I$  cases are shown by pink dotted line. Note that we plot logarithmic values in Fig. B1, as mentioned above.

800 Note that Franzke (2009) used a similar approach for indices such as the North Atlantic Oscillation, and found a simple relationship between the power spectrum and frequency, consistent with Kolotkov, D. Y. et al. (2016). However, we follow Gilman et al. (1963) to define a relationship between the power spectrum and frequency. This incorporates the lag-1 auto-correlation of the timeseries into the theoretical red noise power spectrum (see below).

### B2.2 Theoretical red noise test

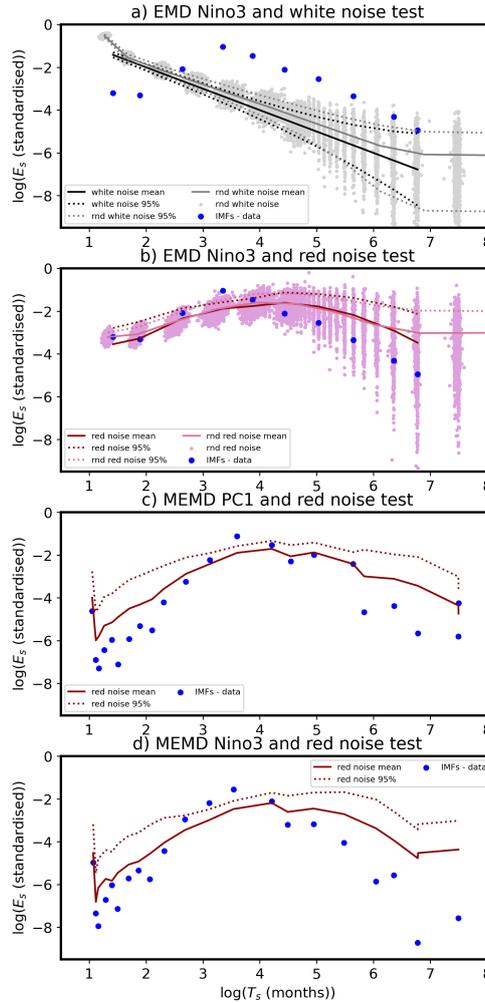

805 Alternatively, one can compute a theoretical power spectrum of the red noise (cf. Gilman et al. 1963)

$$S(\nu) = \frac{1-r^2}{1-2r \cos 2\pi\nu + r^2} \quad (\text{B7})$$

where  $S$  is the power spectrum of red noise,  $\nu = 1/t$  is frequency, and  $r$  is again lag-1 auto-correlation from our data. For each frequency estimate we must multiply  $S(\nu)$  by frequency range ( $\Delta\nu$ ) (cf. Eq. (B2)) to obtain a theoretical estimate of the (mean) energy of the red noise ( $E^{red}$ ) (cf. Kolotkov, D. Y. et al. 2016)

$$810 \quad E^{red}(\nu) = S(\nu)(\nu\alpha - \nu/\beta) \quad (\text{B8})$$

where  $\beta = \sqrt{\nu_s/\nu_{s+1}}$  and  $\alpha = \sqrt{\nu_{s-1}/\nu_s}$  with  $s$  running over frequencies (from higher to lower frequency). Note that since EMD is a dyadic filter (each lower frequency is a half of the previous one; e.g., Flandrin et al. 2004; Rehman and Mandic 2011) both  $\alpha$  and  $\beta$  typically take a value of  $\sqrt{2}$  (consistent with, e.g., Kolotkov, D. Y. et al. 2016). Note that when mode-mixing is

**Figure B1.** Significance tests for EMD and MEMD: (a) white noise significance test and (b) red noise significance test for EMD-IMFs of Niño3 index (blue dots); (c) (theoretical) red noise test for IMFs of PC1 of the combined field (via MEMD; blue dots) (d) (theoretical) red noise test for Niño3 obtained via MEMD (blue dots). (a) black solid line represents the theoretical linear relationship between the logarithms of period ( $T_s$ ) and logarithm of energy density ( $E_s$ ) (Eq. (B3)), black dotted line represents 5<sup>th</sup>-95<sup>th</sup> percentile (Eq. B5), respectively; grey dots represent  $I = L$  realisations of IMFs of white noise timeseries (length is the same as for Niño3 index), whereas grey solid and dotted lines represent their mean and the 5<sup>th</sup>-95<sup>th</sup> percentile, respectively. (b) red solid line represents the theoretical red spectrum energy density (Eqs. (B7-B9)), red dotted line represents the 95<sup>th</sup> percentile (via  $\chi^2$ -test); light pink dots represent  $I = L$  realisations of IMFs of red noise timeseries (Eq. B6; length  $L$  is the same as for Niño3 index), whereas pink solid and dotted lines represent their mean and the 95<sup>th</sup> percentile, respectively. In (c) and (d) the red solid and dotted lines are as in (b) but for the respective data from MEMD. Note that x-axis shows the logarithms of period ( $T_s$ ) ordered from shortest period (highest frequency) to longest period (trend). Also, in (d) IMF22 was too large to fit the graph, but was identified (see Fig. S7, Table S1). For further description of the figure see text.

present (e.g., in this study it is generally present at higher frequencies) this is not necessarily true, hence the use of  $\alpha$  and  $\beta$  in Eq. (B8). Finally,  $E_{red}$  must be scaled such that its total energy is the same as the total energy of our data (e.g., Madden and Julian 1971; Bretherton et al. 1999)

$$E_s^{red} = E_s^{red} \frac{\sum_{s=2}^{s_{max}-1} E_s}{\sum_{s=2}^{s_{max}-1} E_s^{red}} \quad (\text{B9})$$

where  $s_{max}$  is the number of IMFs (as above), and  $s$  represents the  $s^{th}$  IMF of frequency  $\nu_s$ , and  $E_s$  was defined above (Eq. (B1)). Note that we scale  $E_s^{red}$  from total energies of IMFs between  $s = 2$  and  $s = s_{max} - 1$  as the last IMF is typically a trend/residual and the first IMF does not necessarily follow the distribution correctly (but including the two usually does not significantly alter the results).  $E_s^{red}$  is shown in Fig. B1b as red solid line.

This red noise test is typically used in climate science to determine the significance of power spectra peaks in our data (using  $S(\nu)$  from Eq. (B7)), and it differs from the red noise test of Kolotkov, D. Y. et al. (2016) as it takes into consideration the lag-1 auto-correlation of the data. If the cosine function in the  $S(\nu)$  (Eq. (B7)) is expanded into Taylor series ( $\cos 2\pi\nu \approx 1 - (2\pi\nu)^2/2 + \dots$ ) one can realise that for large  $\nu$  (high frequencies)  $S(\nu)$  indeed reduces to the spectrum  $\gamma\nu^{-2}$  (with  $\gamma$  a constant) suggested by Kolotkov, D. Y. et al. (2016); Franzke (2009). However, for low frequencies (small  $\nu$ ) they do not agree well and ultimately  $S(\nu)$  also becomes a constant (see Fig. B2 for comparison). Furthermore, as  $S(\nu)$  depends on lag-1 auto-correlation ( $r$ ) we can see from Eq. (B7) that for  $r = 0$ ,  $S(\nu) = 1$ , i.e., it reduces to the power spectrum of the white noise. This means that this theoretical test can potentially be used for testing the significance of the data that corresponds to either white or red noise.

The significance of the IMFs from the input data is tested using  $\chi^2$ -test, where  $s^{th}$  IMF's  $\chi_s^2$  value for the (one-tailed) 95<sup>th</sup> percentile is computed from  $\text{DoF}_s = L_{eff} E_s$  degrees of freedom (instead of  $LE_s$  as was the case for white noise, due to strong correlations between neighbouring data-points; Bretherton et al. 1999; Wu and Huang 2004; Kolotkov, D. Y. et al. 2016), where (Bretherton et al., 1999)

$$L_{eff} = \frac{1 - r^2}{1 + r^2} L. \quad (\text{B10})$$

Then we multiply the expected red noise curve  $E_s^{red}$  by  $\chi_s^2/\text{DoF}_s$  (e.g., Madden and Julian 1971; Bretherton et al. 1999) to ultimately obtain a threshold for 95<sup>th</sup> percentile (red dotted line in Fig. B1b). Note that for  $\text{DoF}_s < 1$  we set  $\text{DoF}_s = 1$  (to avoid numerical issues). The IMFs derived from the data (blue dots in Fig. B1b) that exceed the red noise threshold (i.e., lie above the red/pink dotted line in Fig. B1b) are considered significant at 95<sup>th</sup> percentile (one-tailed).

Fig. B1b shows that the two (synthetic and theoretical) red noise tests (for Niño3 index via EMD) are somewhat comparable and that the majority of the input (e.g., Niño3 index) data (blue dots) lies within the red noise range (i.e., within the pink-dots, and below the pink/red dotted line). However, we can identify one IMF (period  $\sim 31$  months or  $\sim 2.5$  years) that is above the red noise threshold and well within the typical ENSO timescale (2-8 years), suggesting quasi-periodic behaviour (oscillations).

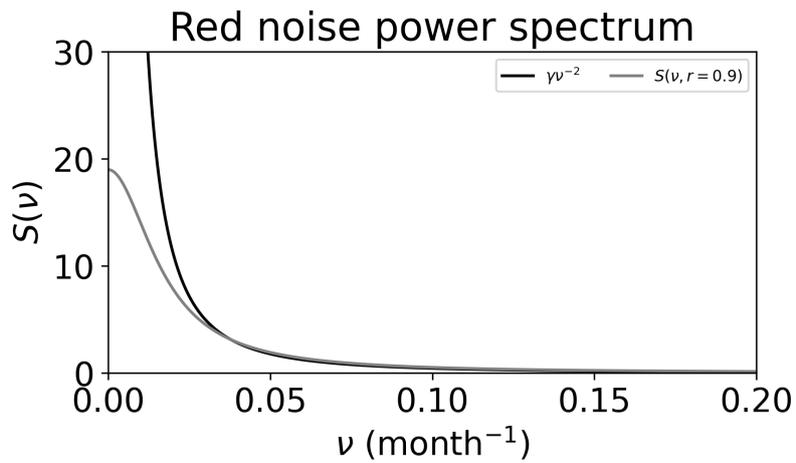

Similarly, we can identify one significant IMF (via MEMD) in the PC1 (Fig. B1c) of the 3-variable field (discussed in section 2.1, Appendix A) with a period of  $\sim 37$  months ( $\sim 3$  years; i.e., IMF13). Note that we use PC1 of the combined field as an example of the overall tropical Pacific IMFs (via MEMD) in Fig. B1c, since PC1 strongly dominates the EOF decomposition

of the SST field there. One could potentially also compute significant modes by computing red noise test at each grid-point and then average the results over all grid-points, but we have not used this here. Instead, we use an additional test on map-plots in section 3 (Fig. 2; Figs. S2-S4 in supplement), where we identify *potentially* “oscillatory” grid points and use grey shading on areas that are well represented with red noise alone (i.e., not significant).

Upon a reconstruction of IMFs for the x-y-t SSTs (Eq. A4), we can average SSTs over the Niño3 region (using the same IMFs obtained via MEMD; see also section 2.2). This yields two significant modes (i.e., IMF12, IMF13; Fig. B1d) both within the quasi-biennial QB and LF/QQ range of the ENSO (Allan, 2000; Jajcay et al., 2018), i.e., with periods of  $\sim 22$  and  $\sim 34$  months ( $\sim 2$ -3 years), respectively. This means that Niño3 index has 2 significant modes of variability (identified via MEMD), but the region of significance is narrow (small) for the  $\sim 22$  month-mode (IMF12; see Fig. S2), thus it is not apparent in the PC1 test that encompasses the whole tropical Pacific (Fig. B1c). The latter serves as an additional (more subjective) test for quasi-periodic modes of variability across the tropical Pacific, which suggests that IMF12 is only marginally significant and only in the Niño3 region (Fig. S2). Similarly, another (more subjective) test was used to make sure that the two quasi-periodic modes identified are well separated (in terms of timescale) from the other modes (and from each other) to avoid identifying mixed modes as significant quasi-periodic modes of variability (see below).

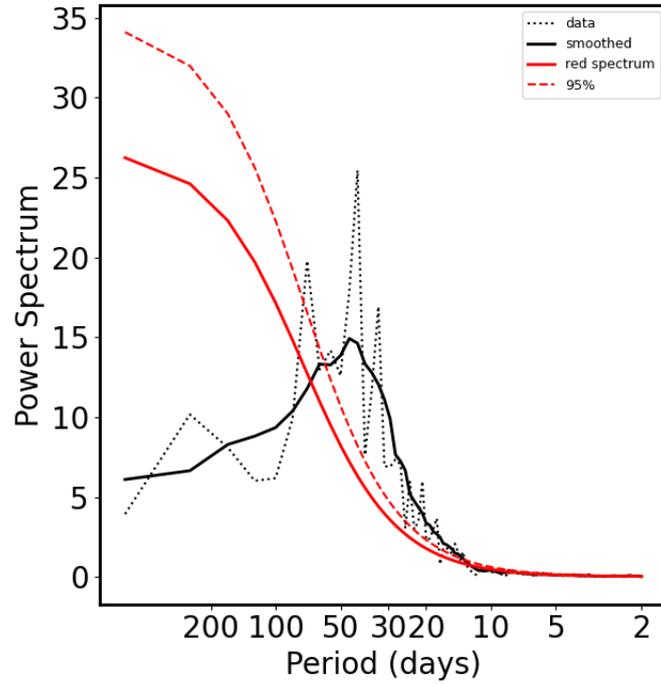

Note that we do not necessarily expect exactly the same results from EMD (Fig. B1b) and MEMD (Fig. B1d) methods since the MEMD finds a “synchronised” signal within the tropical Pacific and across different variables, whereas EMD only analyses the 1-D Niño3 timeseries. This is also true for the number of IMFs obtained via the two different methods. MEMD yields significantly more IMFs as EMD (22 versus 10), which is likely a result of inputting several different timeseries with different timescales, especially in the high-frequency range here (i.e., periods shorter than about 8 months). For example, wind stress can be much noisier than SSTs (or different parts of the tropical Pacific have different variabilities) and can thus lead to identification of several high frequency modes of variability. This can then result in mode-mixing in that frequency range (see somewhat overlapping and close blue dots in Fig. B1c,d) if timescale separation is not clear across different input timeseries, and can ultimately yield more modes (here 22) than when only one timeseries is considered (here 10).

Nonetheless, the two methods agree on the quasi-periodic timescale of 2-3 years in the Niño3 region. This is also consistent with the significant periods inferred from the usual power spectrum analysis of the Niño3 index (1-D) obtained via Fourier Transform (Fig. B3; significant peak in black solid line (power spectrum of Niño3 index) is above the red dashed line (red noise one-tailed 95% threshold)), as well as via a 1-D wavelet transform (not shown).

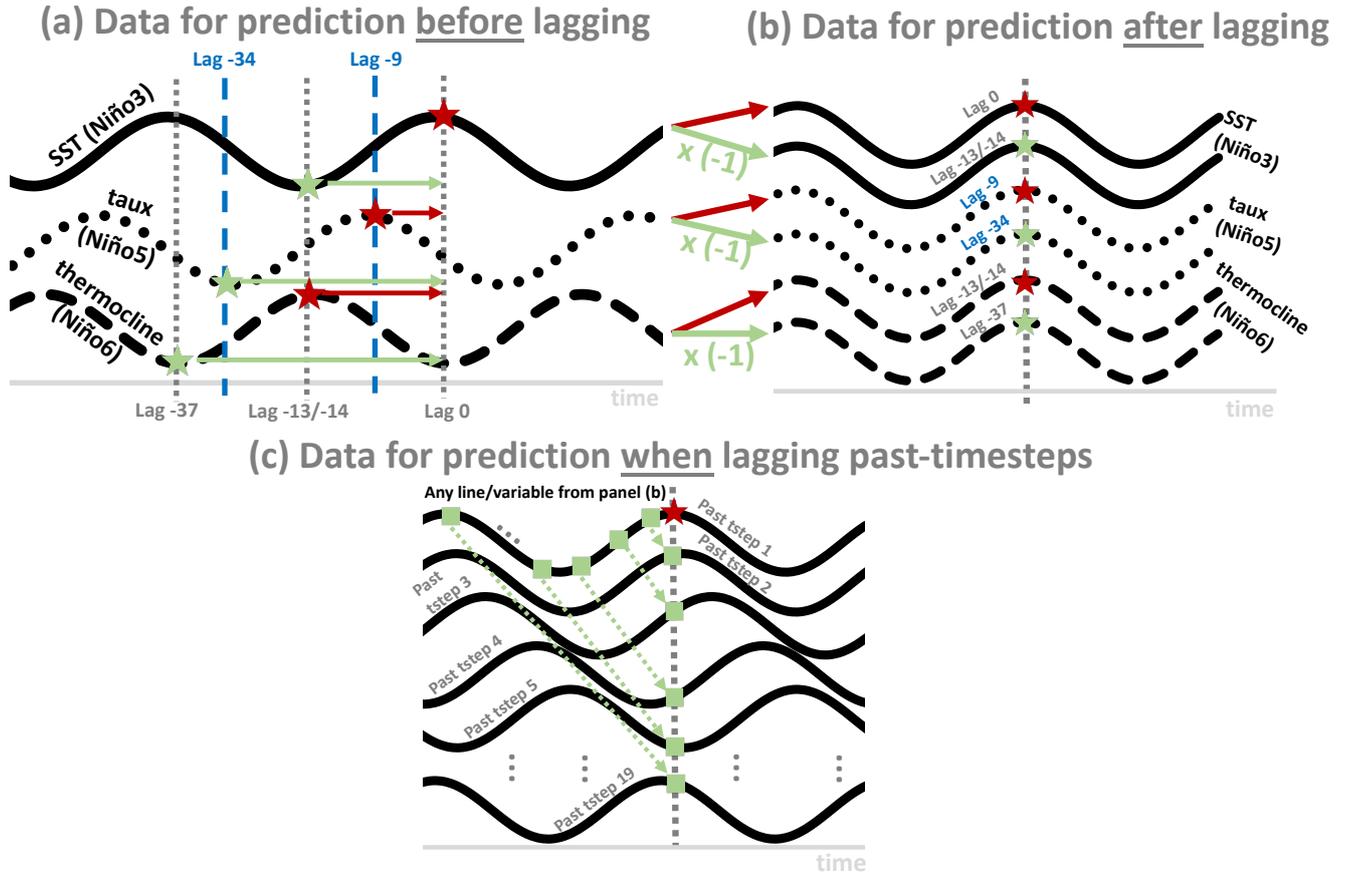

**Figure B2.** Red noise power spectrum ( $S(\nu)$ ) for (black line)  $S(\nu) = \gamma\nu^{-2}$ , and (grey line)  $S(\nu, r)$  from Eq. (B7) for  $r = 0.9$ .  $\gamma$  was estimated as a ratio between the integrated power spectra of the two spectra for frequencies higher than 0.02/month ( $\gamma = \sum_{\nu} \nu^{-2} / \sum_{\nu} S(\nu, r)$ ) where the two power spectra generally agree well.

## Nino3 OBS

**Figure B3.** Power spectrum of Niño3 index. The power spectra are first computed for 500-months long chunks (overlapped by 250 months) and then averaged over all cases (grey solid line). The black solid line represents a 10-point running mean of the black dotted line (to increase the number of degrees of freedom, which is  $f_{\omega}L/0.5L_{\text{chunk}} = 10 \times 1680/250 \approx 67$ ; see also Boljka et al. 2021). The red solid and dashed lines represent the theoretical red noise test and its (one-tailed) 95<sup>th</sup> percentile, respectively.

## Appendix C: Simple statistical prediction model

**Figure C1.** A schematic of the procedure for lagging the data for predictors (relative to a predictand, SST (Niño3)), before inputting them into the simple (multi-linear) statistical prediction model. Black solid lines represent idealised SST (Niño3), black dotted lines represent idealised  $\tau_x$  (Niño5), and black dashed lines represent idealised thermocline depth (Niño6). Vertical lines in (a) represent different lags (as specified). Similarly, stars represent locations of maximum (dark red) and minimum (light green) correlations of different variables with SST (Niño3). These peaks/minima are then lagged according to the identified lag of the maximum/minimum correlation as corresponding arrows show, i.e., they are “moved” towards lag 0. This yields two timeseries from each variable (see transition between (a) and (b)), where the minimum correlations are multiplied by (-1). (b) shows the predictors data as they were input into the statistical prediction model – when using only one past timestep. Note that top black solid line here is lagged by a specific lead time relative to the predictand (if lead time is 0 then predictand equals the top line). (c) shows how each of the lines from (b) (top line in (c)) can be further lagged with its past timesteps (light green squares and subsequent lines in (c) – see arrows). This yields up to 19 more timeseries from each timeseries in (b). For more details see the text.

875 The simple (multi-linear regression) statistical prediction model is constructed as follows. We first prepare timeseries that we can input into the statistical prediction model based on multi-linear regression the following way (Fig. C1; see also Omrani

et al. 2022). First, we lag the input timeseries relative to the SST (Niño3) based on the lag of the maximum correlation of data band-pass-filtered (smoothed) in 25-52.5 months band. We capture both the first maximum (i.e., the strongest positive correlation) and minimum (i.e., the strongest negative correlation) of the correlation between the different timeseries, which includes a full wave/oscillation (Fig. C1a). This generates 6 predictors for the SST (Niño3) (the predictand): SST (Niño3) max at lag 0 months, SST (Niño3) min at lag -14 months,  $\tau_x$  (Niño5) max at lag -9 months,  $\tau_x$  (Niño5) min at lag -34 months, thermocline depth (Niño6) min at lag -13 months, and thermocline depth (Niño6) max at lag -37 months. Note that this yields better results than if only half of the lags (i.e., half of the oscillation) were used (not shown). The results from the prediction based on these 6 predictors are compared with the prediction of SST (Niño3) from SST (Niño3) at lag 0 alone.

885 By lagging the data we generate timeseries of 6 predictors and the predictand that have maximum correlations at lag zero (Fig. C1b). We can then input the timeseries into the multi-linear regression model and predict SST (Niño3) at different lead times (1, 2, 3, ... , 30 months). For each lead time we construct a new prediction model.

To improve predictions we use the predictors' data from several past timesteps (i.e., use each of the predictors at months ..., -19, -18, ..., -1 relative to the predictand; Fig. C1c). This can increase the 'number' of predictors significantly, but must be used carefully (i.e., sensitivity to the number of the past timesteps used should be tested).

890 The above yields the predictions of SST (Niño3) for different lead times and can then be used to assess the skill of the prediction – see section 4.2.

*Author contributions.* LB performed the analysis, prepared the figures, and wrote the first draft of the manuscript. NEO and NSK provided additional insight and helped improve the manuscript for the final version.

895 *Competing interests.* The authors declare no competing interests.

*Acknowledgements.* This work was supported by the Trond Mohn foundation (project BCPU, grant number BFS2018TMT01) and was performed on NIRD/Sigma2 (project NS9039K). We thank three anonymous reviewers for their constructive comments that helped improve the original manuscript. We also thank Lander Crespo for helpful discussions, and Ingo Bethke for the help with the data.
